toward HCHO is evaluated in a 3 $m³$ test chamber, confirming the practicability and reliability of the InAG sensor. This work provides an effective strategy for the development of low-power-consumption ppb-level gas sensors.

KEYWORDS: *In2O3 nanorods, supramolecularly functionalized graphene, formaldehyde sensing, room temperature, visible-light-driven heterojunctions*

■ **INTRODUCTION**

Formaldehyde (HCHO), one of the most toxic indoor pollutants, is widely derived from the volatilization of interior decoration materials such as furniture, paint, and wallpaper.^{[1](#page-11-0)} The recommended exposure limit (REL) for HCHO given by the World Health Organization (WHO) is 80 ppb. 2 Therefore, it is imperative to develop high-performance ppb-level HCHO monitoring sensors.

Conventional chemiresistive gas sensors based on metal oxide semiconductors (MOS) are one of the most intensively studied in the field of gas sensors.^{[3](#page-11-0)} However, high operating temperatures are required due to very few reactive oxygen species reacting with the gas on MOS's surface at room temperature (RT). Typically, the consequent problems of shortened lifetime, high power consumption, and poor safety further limit the application of MOS-based gas sensors.^{[4](#page-11-0),[5](#page-11-0)} Thus, room temperature detection of HCHO presents unique advantages owing to its low power consumption and wide safety margins. Light illumination is an important strategy for achieving RT sensing.^{[6](#page-11-0),[7](#page-11-0)} Li et al.⁸ prepared Au-TiO₂ hollow nanospheres by the template method and achieved good detection of HCHO under 365 nm light. Despite these advances, the application of most MOS-based sensors is still

limited due to their low sensitivity, relatively high practical limits of detection (pLOD), and poor selectivity. Precise detection of HCHO below 100 ppb at RT is still challenging and urgently needed.

To achieve better gas-sensing properties, hybridizing MOS and graphene nanosheets to form heterojunctions is consid-ered an effective way.^{[9](#page-11-0)[,10](#page-12-0)} Graphene has attracted much attention in the field of RT gas sensing owing to its atomically thick honeycomb lattice structure, high specific surface area, and excellent electrical conductivity.^{[11](#page-12-0),[12](#page-12-0)} In our previous work, we reported that the supramolecular assembly of a dipole (e.g., 5-aminonaphthalene-1-sulfonic acid, etc.) with reduced graphene oxide (rGO) can significantly promote its charge transfer rate.^{13,[14](#page-12-0)} Compared with other MOS, indium oxide (In_2O_3) , as a typical n-type semiconductor with excellent optoelectronic properties, good thermal stability, low resis-

tivity, and high catalytic activity, is regarded as one of the most promising HCHO-sensing materials.^{15,[16](#page-12-0)} Furthermore, In_2O_3 is easy to modulate for defects due to the nonstoichiometric phase structure and readily obtains a homogeneous morphol-

ogy by liquid phase methods.^{[17,18](#page-12-0)} A recent study suggests that In_2O_3 containing defects has a strong adsorption capacity for $HCHO₂⁵$ $HCHO₂⁵$ $HCHO₂⁵$ which can effectively improve the selectivity without additional molecular filter membrane coverings, 19 etc. For the past few years, some works have demonstrated that $In_2O_3/$ rGO composites exhibit high room temperature gas responsivity.[20](#page-12-0),[21](#page-12-0) However, the relatively higher pLOD still limits their further application. To the best of our knowledge, no one has tried to combine In_2O_3 with rGO for room temperature HCHO sensing so far.

In general, the specific surface area of nanoparticles increases with the decrease of size. 22 Hence, it is believed that when small size nanoparticles are selected to assemble with graphene, a larger interfacial contact area and more heterojunctions of In_2O_3/rGO will be obtained, which should be beneficial to improve the gas-sensing properties. Therefore, the preparation of smaller In_2O_3 nanoparticles to assemble with 5-aminonaphthalene-1-sulfonic acid (ANS)-modified graphene nanosheets forming more interfaces of heterojunctions could be a good approach to verify the impact of heterojunctions on gas sensing.

In this work, inspired by the above speculations, we designed and prepared visible-light-driven (VLD) heterojunctions of InAG which was composed of functionalized graphene nanosheets and ultrasmall In_2O_3 nanorods with an average diameter of 3.2 nm which is lower than the Debye length. The corresponding InAG-based gas sensor was fabricated for ppblevel room temperature formaldehyde sensing. The InAGbased sensor exhibited outstanding HCHO-sensing properties under 405 nm illumination at room temperature and behaved with remarkable practicability and reliability in a 3 $m³$ test chamber. The gas-sensing mechanism of InAG has been proposed based on the measurement with ultraviolet photoelectron spectroscopy (UPS) and the literature. It is illustrated that the generation of more interfacial depletion layers and the implementation of more efficient charge transfer are jointly responsible for the ultrasensitive room temperature HCHOsensing properties of InAG.

■ **RESULTS AND DISCUSSION**

Synthesis and Sensor Fabrication. [Figure](#page-3-0) 1 illustrates the process flow for the preparation of InAG nanohybrids and an RT gas sensor. To solve the problem of poor dispersibility of graphene, ANS molecules are attached to graphene through *π*−*π* stacking supramolecular interactions. The negatively charged $-SO_3$ ^{- \degree}groups provide sufficient electrostatic repulsion to maintain excellent water dispersibility of ANS/ rGO nanosheets [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S1). As shown in [Figure](#page-3-0) 1, the ANS/ rGO and the In_2O_3 show opposite charges, indicating that they can be easily assembled by electrostatic interaction.

Characterization of Gas-Sensing Materials. The crystal structures of the synthesized samples were determined by XRD analysis. As shown in [Figure](#page-3-0) 2a, the diffraction peaks of the In_2O_3 nanorod precursor can be correlated with $In(OH)_3$ (ICDD card no. 01-085-1338). The highest-intensity diffraction peak corresponding to the (200) crystal plane indicates that $In(OH)_{3}$ grows along the [100] orientation.^{[9](#page-11-0)} According to ICDD card no. 00-006-0416, the diffraction peaks of calcined In₂O₃ nanorods at 2θ of 30.58°, 35.46°, 51.03°, and 57.55° match with the crystal faces of (222), (400), (440), and (622) of the cubic In_2O_3 . After assembling with ANS/rGO nanosheets, the diffraction peaks of InAG nanohybrids presented as similar to those of the pure In_2O_3 nanorods. Furthermore, no characteristic diffraction peaks of carbon species are observed in the hybrids due to the relatively low content of ANS/rGO. As shown in [Figure](#page-3-0) 2b, the reduction of GO and the presence of ANS/rGO in InAG nanohybrids are confirmed by Raman spectroscopy. In the spectrum of In₂O₃ nanorods, the Raman peaks at 306 cm⁻¹ (E_{1g}) , 363 cm⁻¹ (E_{2g}) , 492 cm⁻¹ (A_{1g}) , and 624 cm⁻¹ (E_{2g}) correspond to the optical phonons associated with the cubic crystal structure of In_2O_3 .^{[23](#page-12-0)} The peaks at 306 and 363 cm⁻¹ are attributed to the bending vibration of the $InO₆$ octahedron [δ (InO₆)] and the stretching vibration of the indium− oxygen−indium bond [*υ*(In�O�In)], respectively.[9,](#page-11-0)[24](#page-12-0) The peaks at 492 and 624 cm^{-1} are assigned to the stretching vibration of the InO₆ octahedron $[\upsilon(\text{InO}_6)]^{25}$ $[\upsilon(\text{InO}_6)]^{25}$ $[\upsilon(\text{InO}_6)]^{25}$ As expected, InAG displays two main D-band and G-band peaks at 1341 and 1599 cm[−]¹ , respectively, confirming the successful assembly of In_2O_3 nanorods on ANS/rGO nanosheets. The D-band is related to structural defects in graphene, and the Gband is attributed to the first-order scattering of the E_{2g} mode of the $sp²$ bonds of carbon atoms.^{[26](#page-12-0)} The peak intensity ratio of the D-band and G-band (I_D/I_G) is customarily used to evaluate the degree of disorder and defects in graphitic structure. The I_D/I_G values of rGO, ANS/rGO, and InAG are all higher than that of GO, which indicates that GO has been successfully reduced.^{[27](#page-12-0)} The FTIR spectra of the samples are shown in [Figure](#page-3-0) 2c. In the spectrum of rGO, the characteristic absorption band at 1568 cm⁻¹ is attributed to C=C skeleton vibration. 26 Moreover, the characteristic peaks of oxygencontaining groups in GO, including C — O (1050 cm⁻¹), $C =$ O (1740 cm⁻¹), and O—H (3400 cm⁻¹),^{[26](#page-12-0),[28](#page-12-0)} are not found in rGO, indicating that graphene oxide is reduced. Compared with rGO, the broader peak at 3420 cm⁻¹ of ANS/rGO can be attributed to N-H stretching vibration from the ANS molecule, confirming the successful assembly of rGO with the ANS molecule. For In_2O_3 nanorods and InAG nanohybrids, the well-identified vibrational bands around 420, 567, and 604 cm⁻¹ can be attributed to In-O lattice vibrations of In_2O_3 .^{[29](#page-12-0)} A broad peak corresponding to the O—H stretching vibration appeared at 3400 cm[−]¹ , which may be related to the adsorbed water vapor and hydroxyl groups on the surface of In_2O_3 nanomaterials.^{[29](#page-12-0)}

The morphology and microstructure of the prepared samples were observed by SEM, AFM, and TEM. It can be seen from [Figure](#page-3-0) 2d that rGO has an obvious stacking phenomenon. The height of the representative rGO measured by AFM in [Figure](#page-3-0) 2f is 35 nm. In contrast, the morphology of the as-prepared ANS/rGO is typical of graphene sheets ([Figure](#page-3-0) 2e), demonstrating that the supramolecular assembly of ANS molecules can prevent severe stacking between rGO sheets. The AFM height profile in [Figure](#page-3-0) 2g shows that the ANS/rGO nanosheet has a thickness of 4 nm. [Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S2 exhibits the SEM images of In_2O_3 nanorods, InAG, In_2O_3 microrods, and InMAG. It can be seen from [Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S2a that the morphologies of the as-prepared In_2O_3 nanorods are tiny nanoparticles. For the InAG nanohybrids, In_2O_3 nanoparticles are embedded in the network composed of ANS/rGO nanosheets [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S2b), which proves that the anchoring of In_2O_3 on ANS/rGO nanosheets through electrostatic interaction is an effective strategy. Owing to the small size of In_2O_3 nanorods and the good dispersion of ANS/rGO nanosheets, large heterojunctions are formed at the interface, which is favorable for gas sensing. As a comparison, SEM images of In_2O_3 microrods and InMAG are shown in [Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S2c,d. The

Figure 3. (a) UV–vis DRS and (b) Kubelka–Munk plots of InAG nanohybrids, In₂O₃ nanorods, and In(OH)₃. (c) High-resolution O 1s spectra of InAG and In₂O₃ nanorods.  In_2O_3 formed by the calcination of $In(OH)_3$ exhibit a nanorodlike structure ([Figure](#page-3-0) 2h). [Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S3 shows that the average length and diameter of In_2O_3 are 13.6 and 3.2 nm, respectively, which are less than the Debye length (25 nm³⁰) of In_2O_3 . Furthermore, the TEM image of InAG nanohybrids [\(Figure](#page-3-0) [2](#page-3-0)i) also clearly demonstrates that the In_2O_3 nanorods are anchored on the wrinkled ANS/rGO nanosheets, which is consistent with the SEM image. In the high-resolution TEM (HRTEM) image of InAG nanohybrids [\(Figure](#page-3-0) 2j), the lattice fringes with spacings of 0.292 and 0.413 nm correspond to the (222) and (211) crystal planes of cubic In_2O_3 , respectively. The selected area electron diffraction (SAED) pattern in [Figure](#page-3-0) 2k is composed of multiple concentric rings corresponding to the (211), (222), (400), (440), and (622) crystal plans of In_2O_3 , separately, revealing the polycrystalline structure of In_2O_3 .^{[31](#page-12-0)} [Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S4 presents the HAADF STEM image and EDS mapping patterns of InAG nanohybrids, which clearly show the uniform distribution of In, O, C, N, and S elements. The In and O elements are derived from In_2O_3 nanorods, and the C, N, and S elements are derived from rGO and ANS molecules, indicating the successful preparation of InAG nanohybrids.

As shown in Figure 3a, InAG nanohybrids, In_2O_3 nanorods, and $In(OH)$ ₃ have absorption in the UV region within the range of 200–400 nm, while the absorption of In_2O_3 and InAG in the visible range (400−500 nm) is significantly enhanced. The appearance of the absorption band means that the 400− 500 nm photon energy is greater than the band gap of the semiconductor, indicating that electrons in In_2O_3 can transfer from the top of the valence band to the bottom of the conduction band.[32](#page-12-0) The band gaps can be estimated by the Kubelka−Munk function formula (see the [Supporting](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) [Information](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) for details). $33,34$ $33,34$ As shown in Figure 3b, the forbidden band widths of $In(OH)_3$, In_2O_3 , and InAG are 3.73, 2.67, and 2.38 eV, respectively. According to previous studies,^{[15,34](#page-12-0)} the reduction of the band gap of In_2O_3 nanorods

after calcination can be attributed to a large amount of oxygen vacancy (O_{vac}) defects. New donor energy levels can be formed by O_{vac} in the band gap of In_2O_3 , expanding the light absorption range and improving the separation efficiency of photogenerated electrons and holes.

The EPR approach can identify oxygen vacancies by capturing unpaired electrons in the sample. The *g*-factor provides magnetic information on the material and can be calculated from the resonance conditions (see the [Supporting](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) [Information](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) for details).[15](#page-12-0),[33](#page-12-0) As presented in [Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S5, InAG exhibits a *g* signal (2.003) at the magnetic field of 3511 G after calcination owing to the presence of singly ionized oxygen vacancies.^{[35](#page-12-0)} [Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S6a shows the full XPS spectra of $In(OH)_{3}$, In2O3 nanorods, and InAG. The high-resolution spectrum of In 3d ([Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S6b) shows two peaks at 452.09 and 444.53 eV which are attributed to the spin–orbit splitting of In $3d_{3/2}$ and In $3d_{5/2}$ in In₂O₃, respectively.^{[18](#page-12-0)} After assembling with ANS/ rGO, the peak position of In 3d shifted slightly toward the lower binding energy owing to the electron transfer and interaction between In_2O_3 and ANS/rGO.^{[21](#page-12-0),[23](#page-12-0)} The highresolution O 1s spectra of In_2O_3 and InAG (Figure 3c) are fitted to three peaks at 529.86, 531.36, and 533.16 eV, corresponding to lattice oxygen (O_{lat}) , oxygen vacancies (O_{vac}) , and adsorbed oxygen species (O_{ads}) , respectively.^{[23](#page-12-0)} The peak position and O_{lat} , O_{vac} , and O_{ads} species relative contents are listed in [Table](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S1. The O 1s spectrum of $In(OH)_{3}$ is fitted to two peaks at 531.44 and 532.46 eV ([Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S6c), corresponding to In-OH and surface-adsorbed oxygen/ water, 36 respectively. In the C 1s spectrum of InAG [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) [S6d](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf)), three peaks with binding energies at 284.81, 286.16, and 288.86 eV are assigned to $C=C/C-C$ $(\mathrm{sp}^2/\mathrm{sp}^3$ hybridized carbon), C —O (hydroxyl or epoxy carbon), and $C=O$ (carboxyl) groups, respectively.^{9,[32,37](#page-12-0)} The N 1s peak at 400.57 eV and the S 2p peak at 167.78 eV can be observed in the spectrum of InAG ([Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S6e,f), proving the successful assembly of ANS/rGO nanosheets and In_2O_3 nanorods.

Figure 4. (a) Typical responses of rGO, ANS/rGO, In₂O₃ nanorods, In₂O₃/rGO, and InAG after exposure to 500 ppb HCHO. (c) Real-time response curves of the InAG sensor toward different concentrations of HCHO at RT and (d) corresponding linear relationship between concentration and response. (e) Repeatability of InAG nanohybrids toward 500 ppb HCHO at RT and (f) corresponding response/recovery times for each cycle. (g) Selectivity of the InAG sensor toward 500 ppb HCHO and 10 ppm of various interfering gases. (h) Sensor response toward 100 ppb HCHO in the relative humidity range 20− 90% RH. (i) Long-term stability of the sensor toward 100 ppb HCHO for up to one month at RT.

UPS was used to confirm the band structure of In_2O_3 and ANS/rGO, as well as the charge transfer between them. The secondary electron emission spectra ([Figure](#page-5-0) 3d) and valence band spectra [\(Figure](#page-5-0) 3e) can be obtained from the UPS spectrum of In_2O_3 and ANS/rGO in [Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S7.^{[38](#page-12-0),[39](#page-12-0)} The work functions (Φ) of In₂O₃ and ANS/rGO are calculated to be 4.12 and 4.62 eV. At the composite heterojunction interface, electrons will migrate from In_2O_3 to ANS/rGO. The position of the top of the valence band (E_v) with reference to the Fermi level position (*E*^f) is extracted from the onset energy of the valence band edge (E_{onset}). The E_{onset} values of In₂O₃ and ANS/rGO are 2.18 and 0.05 eV, respectively ([Figure](#page-5-0) 3e). See the Supporting [Information](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) for detailed calculations of Φ and *E*v. Based on the calculation results of UPS and UV−vis DRS tests, the schematic diagram of the energy band of In_2O_3 and ANS/rGO is shown in [Figure](#page-5-0) 3f.

Gas-Sensing Performance. [Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S8a displays the current−voltage (*I*−*V*) characteristic curves of the nanohybrids under dark and different wavelengths of visible light illumination (1 mW cm[−]²). The currents of the sensor increase significantly after being exposed to 405 and 460 nm visible light illumination, and the photocurrent decreases with the increase of visible light wavelength. The electrical properties of the InAG-based sensors were further tested under 405 nm illumination with different power densities [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S8b). The *I*−*V* characteristic curves show that the photoresponse increases with the increase of power density, which can be attributed to the transition of more electrons in the valence band when the power density increases. All *I*−*V* currents show a linear increase with increasing voltage, indicating a good Ohmic contact between the sensing materials and Ag/Pd IEDs. [Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S8c shows the effects of darkness and different wavelengths of visible light illumination (1 mW cm[−]²) on HCHO-sensing properties of the InAG-based gas sensor. The InAG-based sensor exhibits a high response of 2.4 toward 500 ppb HCHO under 405 nm light illumination, which is higher than that under 460 nm light illumination. Nevertheless, it shows no response to the same concentration of HCHO under dark and 530 nm light illumination. The effect of visible light wavelength on gas sensing is related to the energy of the photons. When the photon energy is greater than the band gap of In₂O₃, electrons in the valence band are excited to transition

^aCR, FET, and PEMFC represent chemiresistive, field-effect transistor, and proton exchange membrane fuel cell type gas sensors, respectively. *b*_{conc} : concentration</sub> ζ is a comparison the evaluation of response i conc.: concentration. ^cFor ease of comparison, the evaluation of response is converted as A, response = R_a/R_g ; B, response = R_g/R_s ; and C, response = $I_g - I_a (\mu A)$. ^{*d*}D_R represents the detection range and is taken from the sensor's real-time response curves for different concentrations of formaldehyde.

to the conduction band to produce photogenerated electron− hole pairs. The photogenerated electrons are captured by adsorbed oxygen to produce reactive oxygen which can react with formaldehyde. The sensing performance of the sensor decreases with the increases of wavelength of visible light because only fewer electrons can be excited by the long wavelength light (low energy wavelength). In view of the above results, 405 nm light illumination was adopted in the following work. The relationship between light power density and HCHO-sensing response was further explored. As shown in [Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S8d, the responses of the InAG-based sensor toward 500 ppb HCHO under 405 nm light illumination have little dependence on the light power density ranging from 0.25 to 3 mW cm⁻². The highest response value ($R_{\rm a}/R_{\rm g}$ = 2.4) occurs under 1 mW cm⁻² light power density. Thus, 1 mW cm^{-2} is selected as the optimal light power density.

[Figure](#page-6-0) 4a displays the sensing measurement response curves of rGO, ANS/rGO nanosheets, pristine In_2O_3 nanorods, In_2O_3/rGO , and InAG nanohybrids toward 500 ppb HCHO under 1 mW cm^{-2} 405 nm illumination at RT. The pristine In₂O₃ nanorods, In₂O₃/rGO, and InAG nanohybrids exhibit similar response curves toward HCHO. In contrast, the response of InAG nanohybrids is 1.7 and 1.3 times higher than those of pristine In_2O_3 nanorods and In_2O_3/rGO , respectively. In comparison, the responses of InMAG toward HCHO are significantly lower than that of InAG nanohybrids [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) [S8e](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf)), which is attributed to the large area heterojunction of InAG nanohybrids that enhances the sensing capability. In addition, rGO and ANS/rGO nanosheets show no obvious response after being exposed to HCHO. [Figure](#page-6-0) 4b shows the response/recovery resistance curve of the InAG nanohybrid sensor toward 500 ppb HCHO. The resistance of the sensor decreases rapidly after being exposed to HCHO and returns to the initial value after HCHO release, showing n-type semiconductor sensing characteristics. Response/recovery time is an important indicator to evaluate the performance of gas sensors. The response and recovery times of the InAGbased sensor under 405 nm illumination are 119 and 179 s,

respectively. [Figure](#page-6-0) 4c shows the gas-sensing properties of nanohybrids exposed to different concentrations of HCHO under 405 nm illumination. The responses of the nanohybrid sensor increase monotonically with the increase of HCHO concentration in the range 5−800 ppb. There is an excellent positive linear relationship between response value and HCHO concentration, with a slope of 0.00242 ppb[−]¹ and an *R*² of 0.988 ([Figure](#page-6-0) 4d). Moreover, the sensor shows significant response/recovery characteristics even at a trace concentration of 5 ppb HCHO [\(Figure](#page-6-0) 4c). The pLOD is much lower than the HCHO permissible exposure limit of 80 ppb, which has positive significance for the preparation and practical application of trace HCHO sensors. The theoretical LOD of the nanohybrids for HCHO detection is calculated to be 0.13 ppb based on the root-mean-square noise amplitude (rms_{noise}) of the sensor (see the Supporting [Information](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) for calculation details). A comparison of the sensing properties of typical room temperature HCHO sensors reported in recent years is summarized in Table 1. It is worth noting that our sensor exhibits a high response (0.5 ppm, $R_a/R_g = 2.4$) and the lowest pLOD (5 ppb) among the reported HCHO sensors. Excellent sensing properties show a unique competitive advantage in the field of RT formaldehyde sensing.

[Figure](#page-6-0) 4e presents the response/recovery curves of the InAG sensor for 6 cycles toward 500 ppb HCHO under 405 nm illumination. The response values and response/recovery times ([Figure](#page-6-0) 4f) remain stable over 6 cycles, indicating the good repeatability of the sensor. The gas selectivity of InAG nanohybrids was investigated by exposure to 500 ppb HCHO or high concentrations of interfering gases, such as methanol, benzyl alcohol (C_7H_8O) , isopropanol (C_3H_8O) , ethanol, ammonia (NH₃), acetone, benzene (C₆H₆), toluene (C_7H_8) , and ether ([Figure](#page-6-0) 4g). The sensor exhibits outstanding selectivity for HCHO compared to interfering gases, which may be due to the strong adsorption capacity of In_2O_3 for formaldehyde.^{[5](#page-11-0)[,43](#page-13-0)} Furthermore, large-area InAG heterojunctions provide an abundance of adsorption sites for HCHO.^{[54](#page-13-0)} The O_{vac} defects activate the adsorbed oxygen on

the surface of materials under light illumination, facilitating the adsorption and surface reaction of HCHO. $5,55$ $5,55$ The response values of the InAG nanohybrid sensor toward 100 ppb HCHO were measured under different relative humidity (RH) conditions. As shown in [Figure](#page-6-0) 4h, the response decreases gradually as humidity increases from 20% to 90%. Nevertheless, the response of the InAG sensor toward 100 ppb HCHO reaches 1.26 at 90% RH, indicating that the sensor can maintain operation under high humidity conditions. The decrease in response is because the adsorbed water molecules on the surface of sensing materials occupy some active sites, which hinders the adsorption of the supposed oxygen and HCHO molecules.^{[56](#page-13-0)} The stability of the InAG nanohybrids sensor toward 100 ppb HCHO over 30 days was further tested. As shown in [Figure](#page-6-0) 4i, the sensor exhibits good long-term stability with a drop in response value of only about 7% within a month.

To verify the practicability and reliability of the fabricated RT sensor in actual environmental pollutant monitoring, a 3 m3 simulated indoor environmental pollutant test chamber equipped with a temperature and humidity control system and air samplers was used for field detection (Figure 5a). 1.5−8.0

Figure 5. (a) 3 $m³$ test chamber equipped with a temperature and humidity control system and air sampler for the simulation of indoor environmental pollutants. (b) Correlation between sensor response values and spectrophotometric calibration values; the inset shows a colorimetric tube with analytical reagents for formaldehyde concentration.

*μ*L formalin solutions were heated and volatilized to formaldehyde gas of different concentrations. The formaldehyde concentrations (calibration values) in the test chamber were accurately calibrated by phenol reagent spectrophotometry⁵⁷ (see the Supporting [Information](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) for details). The responses of the sensor were brought into the fitting equation ([Figure](#page-6-0) 4d) to obtain the corresponding formaldehyde concentrations (response values). As can be seen from Figure 5b, the response values of the sensor are in excellent agreement with the accurate calibration values, with high accuracy and reliability, and show great practical prospects in pollutant detection.

Formaldehyde-Sensing Mechanism. Here, we propose a mechanism for the enhanced HCHO sensing of InAG nanohybrids under visible light illumination [\(Figure](#page-9-0) 6). The improved sensing properties of InAG nanohybrids can be attributed to more interfacial depletion layers coming from large-area heterojunctions and more efficient charge transfer resulting from visible-light radiation. As one of the mainstream gas-sensing mechanism models, the gas adsorption/desorption model is suitable for metal-oxide-based gas sensors.^{[58](#page-13-0)} To better understand the HCHO-sensing mechanism of InAG nanohybrids, the sensing mechanism of pristine In_2O_3 is first discussed. The abundant O_{vac} defects in In_2O_3 endow it with visible-light absorption properties. Under 405 nm light illumination, electrons in the valence band gain energy and transition to the conduction band to form photogenerated electron–hole pairs. In fresh air, oxygen molecules (O_2) in the surrounding environment will be adsorbed on the surface of In_2O_3 and capture photogenerated electrons in the conduction band to form active oxygen ions. Among these active oxygen ions $(O_2^-, O^-$, and $O^{2-})$, O_2^- is the dominant species.^{39,[59](#page-13-0)} In addition, an electron depletion layer (EDL) is formed on the surface of In_2O_3 , which is helpful for the increase of initial resistance. When exposed to HCHO, O_2 ⁻ on the surface of In_2O_3 oxidizes HCHO molecules to form carbon dioxide $(CO₂)$ and water $(H₂O)⁵⁵$ $(H₂O)⁵⁵$ $(H₂O)⁵⁵$ At the same time, the photogenerated electrons captured by O_2 are released to the conduction band, resulting in the narrowing of the EDL (ntype sensing behavior). The reaction process is shown in eqs 1−4.

$$
hv \to e^-(hv) + h^+(hv) \tag{1}
$$

$$
O_2(g) \to O_2(ads) \tag{2}
$$

$$
O_2(ads) + e^-(hv) \rightarrow O_2^-(ads)
$$
 (3)

$$
O_2^-(ads) + HCHO(g) \to CO_2 + H_2O + e^-
$$
 (4)

On one hand, the superior sensing properties of the InAG sensor compared to pristine In_2O_3 are attributed to ultrasmall In_2O_3 nanorods and more efficient charge transfer among HCHO molecules, In_2O_3 nanorods, and rGO nanosheets. The diameter and length of In_2O_3 nanorods are less than twice the Debye length of In_2O_3 (25 nm).^{[30](#page-12-0)} Therefore, the EDL occupies almost the entire grain, and the potential barrier at the interface formed between In_2O_3 is relatively high. As shown in [Figure](#page-9-0) 6b, when HCHO is introduced to react with O_2 ⁻ (ads), the wider EDL is more sensitive to the released electrons, and the potential barrier decreases sharply. The larger change in the potential barrier at the grain boundaries increases the response during the aerodynamic reaction. In addition, organic molecules as surface dopants can effectively modulate the electronic properties of graphene.⁶⁰ According to the density functional theory (DFT) calculations, 13 13 13 ANS with a donor-*π*-acceptor (D−*π*−A) structure acts as a bridge for charge transfer, accelerating the electron transfer among HCHO molecules, In_2O_3 nanorods, and rGO, which promotes the HCHO-sensing properties of InAG.

On the other hand, large-area heterojunctions drive the generation of more interfacial depletion layers, enhancing the HCHO-sensing properties. According to UPS results [\(Figure](#page-5-0) [3](#page-5-0)f), the work function of ANS/rGO (4.52 eV) is larger than that of In_2O_3 (4.12 eV). In InAG nanohybrids, some electrons migrate from In_2O_3 to ANS/rGO, balancing the Fermi level ([Figure](#page-9-0) 6c). According to our previous work, organic-molecule-modified rGO possesses p-type sensing behavior.^{[12](#page-12-0)} Furthermore, the modification of ANS prevents the stacking of rGO sheets and increases the contact area between ANS/rGO nanosheets and In_2O_3 nanorods. Compared to the large In_2O_3 microrods, ultrasmall In_2O_3 nanorods have a larger interface contact area with the well-dispersed ANS/rGO nanosheets. Thus, large-area p−n heterojunctions and depletion layers are formed at the interface of ANS/rGO and In_2O_3 , and the builtin electric field in the heterojunction leads to band bending at

Figure 6. Enhanced sensing mechanism of InAG nanohybrids. (a) Reaction of HCHO molecules on the surface of InAG nanohybrids under 405 nm light illumination. (b) Changes in EDL thickness and potential barrier of In₂O₃ homojunction in air and HCHO. (c) Energy band diagram of InAG heterojunction in air and HCHO atmosphere.

the interface, which effectively improves the separation efficiency of photogenerated carriers. Similar to what is described earlier, the presence of the depletion layer increases the resistance of sensing materials; electrons released significantly increase the conductivity of the InAG sensor when HCHO molecules are present.

■ **CONCLUSION**

We presented a VLD heterojunction of InAG which was composed of ultrasmall In_2O_3 nanorods and supramolecularly functionalized rGO nanosheets. The InAG-based sensor exhibited outstanding properties toward low concentrations of HCHO under 405 nm illumination, including high response, relatively short response/recovery times, and reliable repeatability, with the advantage of low power consumption. What is commendable is that the sensor realized the ultralow pLOD of 5 ppb toward HCHO at RT. Sensing mechanism studies demonstrated that the generation of more interfacial depletion layers and the implementation of more efficient charge transfer were jointly responsible for the ultrasensitive room temperature HCHO-sensing properties of InAG. The remarkable practicability and reliability of the InAG sensor in monitoring indoor HCHO pollutants were verified by using a 3 m^3 test chamber. This work provides an effective strategy for the development of ultrasensitive RT ppb-level gas sensors.

■ **EXPERIMENTAL SECTION**

Preparation of ANS/rGO Nanosheet Dispersions. Graphene oxide (GO) was prepared from high-purity graphite powder by an improved Hummers' method (for details, see the [Supporting](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) [Information\)](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf). An ANS supramolecular functionalized graphene nanosheet dispersion was synthesized as follows. A total of 90 mg of ANS, 4 mL of GO dispersion (1 mg/mL), and 5 mL of NaOH solution (4 mg/mL) were added to 10 mL of deionized water and stirred for 10 min under 80 °C. Then, 10 mL of the hydrazine hydrate solution $(1.2 \mu L/mL)$ was added dropwise to the above-mixed liquid and stirred for another 1 h. The product was naturally cooled to RT and washed with deionized water by vacuum filtration using a 0.22 *μ*m filter membrane. Subsequently, a homogeneous ANS/rGO nanosheet dispersion was obtained by redispersing the resultant in deionized water. For comparison, rGO was prepared in the same way without adding ANS molecules.

Preparation of In_2O_3 **Nanorods.** 0.3 g of $In(NO_3)_3 \times H_2O$ and 0.14 g of hexamethylenetetramine were added into a flask filled with 5 mL of deionized water and stirred at 100 °C for 2 h. After the solution naturally cooled down below 30 °C, the white solid precipitated product was collected by centrifugation, washed thoroughly with deionized water and ethanol several times, and then dried at 60 °C in air. The obtained samples, the precursor of In_2O_3 nanorods, were calcined in a tube furnace at 200, 300, and 400 °C, separately, for 2 h under an argon atmosphere. The gas-sensing results showed that the In₂O₃ calcined at 300 $^{\circ}$ C had a higher response to formaldehyde [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S9a). Hence, all In_2O_3 used in this work were calcined at 300 $^{\circ}$ C. For comparison, In₂O₃ microrods were prepared using urea instead of hexamethylenetetramine in the synthesis step to verify the

effect of the interface area of the heterojunction formed between In₂O₃ with different sizes and graphene on gas-sensing properties.

Preparation of In₂O₃/ANS/rGO Nanohybrids. 100 mg of In₂O₃ and a certain amount of ANS/rGO dispersion were introduced into 5 mL of deionized water with stirring. The mass ratio of ANS/rGO nanosheets and In_2O_3 were 0.1%, 0.5%, 2.5%, and 12.5%. Then, the mixture was ultrasonicated for 30 min to allow In_2O_3 to evenly adsorb on ANS/rGO nanosheets to obtain assembled $In_2O_3/ANS/rGO$ nanohybrids. The products were collected via centrifugation (10000 rpm) and then dried at 80 °C in air. For comparison, In_2O_3 nanorods/ANS/rGO and In_2O_3 microrods/ANS/rGO were prepared in the same manner. The gas-sensing results ([Figure](https://pubs.acs.org/doi/suppl/10.1021/acsami.3c00218/suppl_file/am3c00218_si_001.pdf) S9b) show that nanohybrids with a mass ratio of 0.5% exhibit a better response to formaldehyde. Here, 0.5% is chosen as the optimal ratio for characterization and sensing tests. For convenience, In_2O_3 nanorods/ANS/rGO and In_2O_3 microrods/ANS/rGO are abbreviated as InAG and InMAG, respectively.

Sensor Fabrication and Performance Measurements. The sensor devices were fabricated using the drip-coating method. Briefly, $2~\mu\text{L}$ of each sensing material dispersion $(100~\text{mg/mL})$ was uniformly drop-coated on a ceramic substrate with 5 pairs of Ag/Pd interdigitated electrodes (IDEs) and dried at 60 °C in air. The gassensing properties of the InAG nanohybrid-based sensor under light illumination were tested by a Keithley 2450 source meter (Tektronix) under an excitation voltage of 0.01 V direct current. The light sources used light-emitting diodes (LED) whose power density can be controlled by an applied voltage and calibrated by a silicon photodiode sensor S120VC (Thorlabs). Dry formaldehyde gas (Dalian Special Gases Co., Ltd.) with a concentration of 50 ppm was selected as the target gas. The gas-sensing measurements were carried out in a homemade sensor test system in ambient air with relative humidity (RH) of 40 \pm 5% at RT (25 \pm 3 °C). In addition, the applied bias voltage of the sensors during the tests was 0.01 V, showing a low power consumption. In the process of the gas-sensing test, the photocurrent value of nanohybrids reached a stable platform under 405 nm illumination (power density: 1 mW cm[−]²) first, and then, different volumes of 50 ppm formaldehyde gas were injected into the test chamber (17 L) to reach the desired formaldehyde concentration. For volatile organic compounds (VOCs, including ethanol, acetone, benzene, etc.), the liquids were injected on a heating plate inside the test chamber through a microsyringe and volatilized for detection. The gas response (*S*) to reducing gases of the sensor devices is defined as $S = R_a/R_g$, where R_a and R_g represent the stable resistance of the sensors in the air and target gas atmosphere, respectively. The response time (t_{res}) and recovery time (t_{rec}) are defined as the times required for 90% of a full response and for a full recovery, respectively.

Materials Characterization. The crystalline structures of the asobtained samples were characterized by an X-ray diffractometer (XRD, Bruker D8 Advance) with Cu K*α*. Fourier transform infrared spectra were obtained by an infrared spectrometer (FTIR, Vertex 70). The Raman spectra were tested by a Raman spectrometer (Raman, Renishaw inVia) with a 532 nm laser source. The ultraviolet−visible diffuse reflectance spectra (DRS) of the samples were measured by a UV−vis spectrophotometer (UV−vis, Shimadzu UV-2600). The morphology and microstructure of the as-prepared samples were observed using field-emission scanning electron microscopy (FE-SEM, ZEISS Gemini 500) and transmission electron microscopy (TEM, JEM-2100HR). Energy dispersive X-ray spectroscopy (EDS) mapping was analyzed by high-angle annular dark-field scanning transmission electron microscopy (HAADF STEM, FEI Talos F200X). Atomic force microscopy (AFM, Multimode8) was used to measure the thickness and profile of rGO and ANS/rGO nanosheets in ScanAsyst mode. X-ray photoelectron spectroscopy (XPS) and ultraviolet photoelectron spectroscopy (UPS) were characterized using a photoelectron spectrometer (Shimadzu AXIS Supra). XPS was used to analyze the surface elemental composition of the samples with a monochromatic Al/Ag dual anode X-ray source, and C 1s at 284.8 eV was used as a reference. UPS was used to measure the work function of the samples with a He I (21.2 eV) UV light source. *ζ*

potentials of the samples were acquired in ultrapure water via dynamic light scattering (Brookhaven NanoBrook Omni). The oxygen vacancy signals were investigated by electron paramagnetic resonance spectrometry (EPR, Bruker EMXPlus-10/12).
