ABSTRACT

We report our most recent progress and demonstration of a frequency domain multiplexing (FDM) readout technology for transition-edge sensor (TES) arrays, both of which we have been developing in the framework of the X-IFU instrument on board the future Athena X-ray telescope. Using Ti/Au TES micro-calorimeters, high-Q LC filters and analog/digital electronics developed at SRON and low-noise two-stage SQUID amplifiers from VTT Finland, we demonstrated the feasibility of our FDM readout technology, with the simultaneous readout of 37 pixels with an energy resolution of 2.23 eV at an energy of 6 keV. We finally outline our plans for further scaling up and improving our technology in the future.

1. Introduction

Some of the future experiments pursuing scientific breakthroughs in the field of astronomy, cosmology or astroparticle physics will take advantage of the extreme sensitivities of cryogenic detectors such as transition-edge sensors (TES) [1]. A TES is a thin film of superconducting material weakly coupled to a thermal bath, typically at temperatures $T < 100$ mK, that can be used as a very sensitive thermometer by exploiting its sharp phase transition. TES-based microcalorimeters can be used as non-dispersive spectrometers, with desirable features such as high dynamic range, photon collecting area, quantum efficiency and energy resolution. We have been developing TES microcalorimeters for X-ray spectroscopy as backup option for the Athena X-ray Integral Field Unit (X-IFU) [2,3], demonstrating under AC bias resolving power capabilities at a level of $E/\Delta E \simeq 3000$. TES are nowadays being fabricated in large arrays, at a level of hundreds or thousands of detectors in a single wafer batch. This makes it necessary the developments of technologies allowing the readout of a large number of TES with a single readout channel, thus simplifying the harness scheme and thermal load at cryogenic stage. One of such readout schemes is the frequency domain multiplexing (FDM) [4], that we have developed in the framework of Athena X-IFU.

2. FDM readout description and demonstration

In the FDM scheme, the readout of a TES array is performed by placing a tuned high- Q LC band-pass filter in series with each detector and providing an AC bias with an independent carrier in the MHz range. The signals of all the detectors in the readout chain are summed at the input coil of a Superconducting QUantum Interference Device (SQUID), which provides a first amplification at cryogenic temperature. Further amplification and conversion into digital signals are performed at room temperature by a control electronics board, which is also responsible for the bias carrier generation and demodulation of the output comb. We make use of a base-band feedback scheme, where the demodulated TES signals are again remodulated using the same carrier frequencies, compensated with a phase delay and fed back at the SQUID feedback coil, to null the current at the SQUID input: this allows a more efficient use of the SQUID dynamic range and effectively increases the number of pixels readable in a single readout chain.

In our FDM systems the bias frequencies range from 1 MHz to 5 MHz, with a channel separation of 100 kHz, allowing to read up to 40 detectors out of a single readout line. The inductance of the LC filters is fixed to 2 μ H to keep the electrical bandwidth R/L constant,

Fig. 1. Energy spectrum obtained under FDM readout of 37 TES, showing the summed energy resolution of the detectors for photons at Mn-K α lines energies. Bottom panel shows residuals with respect to the model. Each photon energy is estimated using the optimal filter technique [13]. Black dots are the binned data, red curve is the best fit from the Holzer model (green curve) [14] convolved with the energy resolution, obtained minimizing the Cash statistics [15] under the maximum likelihood method. Their grey curve shows a comparison with the typical energy resolution (≈ 150 eV) of traditional solid-state detectors, such as CCD cameras.

and the different frequencies are obtained varying the capacitance. Superconducting transformers connect the LC filters to the TES array to tune the current flowing through the detectors, which is summed at the input of a two-stage SQUID amplifier provided by VTT [5]. Each TES is a Ti/Au bilayer with normal resistance R_N at a level of 150 m Ω and critical temperature $T_C \approx 90$ mK, coupled to an Au or Au/Bi absorber optimized for photon energies ranging from 1 keV to 10 keV. For our experiments we typically employ a ^{55}Fe source generating 5.9 keV photons (Mn-K α lines).

The setups are enclosed in a superconducting shield and suspended via Kevlar wires on the mixing chamber of a dilution refrigerator, operating at a bath temperature of 50 mK. The temperature is controlled via germanium thermistors and eventual remnant magnetic field is canceled out via superconducting Helmholtz coils.

Using such setups we developed and demonstrated effective solutions to issues intrinsic to AC readout that at early stages used to spoil TES performance in multiplexing, *e.g.* high-aspect ratio TES to mitigate non-linear Josephson effects [6] and a Frequency Shift Algorithm (FSA) to limit the impact of intermodulation distortions [7]. We furthermore demonstrated excellent single-pixel spectral performance under AC readout [8], thermal crosstalk [9] and environmental susceptibility levels, in particular to magnetic field [10,11].

Taking on such optimizations allowed us to push the performance of our FDM readout, for which we recently demonstrated a spectral performance with 37 pixels of 2.2 eV at 5.9 keV, or equivalently a resolution of $\approx 0.04\%$, as shown in Fig. 1. More details on the FDM setups and demonstration can be found in [12].

3. Future outlook

Our TES-based FDM readout technology does already satisfy the requirements for space-borne applications such as Athena X-IFU, nevertheless we envisage the possibility for further scaling up, as shown in Fig. 2. For example, it appears to be feasible to expand the readout bandwidth up to 6 MHz, which would naturally allow to accommodate more pixels without a larger impact of electrical crosstalk (ECT). Multiplexing a larger number of pixels represents a challenge also in terms of DAC noise and intermodulation distortions contribution, which we plan to assess once new lithographic components will be fabricated in the near future.

Fig. 2. Expected multiplexing performance as a function of multiplexing factor. The individual contributions (in quadrature) are considered either from an energy resolution budget compiled in the framework of X-IFU and from experimental data.

Further activities currently in progress are tests with multi-channel FDM readout and measurements with a larger number of X-ray lines to verify with precision the calibrability of the TES energy scale. These activities will further validate the viability of our TES-FDM technology not only for astronomy but also for other possible applications, *e.g.* plasma spectroscopy at fusion reactors [16] and solar axion search [17].
