Supporting Information

**ABSTRACT:** Silver oxide cluster cations ( $\text{Ag}_n\text{O}_m^+$ ) can readily be produced by a number of methods including atmospheric-pressure spark ablation of pure silver electrodes when trace amounts of oxygen are present in the carrier gas. Here we determine the equilibrium geometries of  $\text{Ag}_n\text{O}_m^+$  clusters ( $n = 1-4$ ;  $m = 1-5$ ) using accurate coupled cluster with singles and doubles (CCSD) method, while the stabilization energies are calculated with additional perturbative triples correction (CCSD(T)). Although a number of stable states have been identified, our results show that the  $\text{Ag}_n\text{O}_m^+$  clusters with  $m = 1$  are more stable than those with  $m \geq 2$  due to the absence of the terminally attached  $\text{O}_2$  molecule, corroborating recent observations by mass spectrometry. Using the computed structures, we calculate the electrical mobilities of the  $\text{Ag}_n\text{O}_m^+$  clusters and label the values on a respective experimentally determined spectrum in an attempt to better interpret the occurrence of the peaks and troughs in the measurements.

## 1. INTRODUCTION

Silver is a noble metal that has traditionally been employed in a wide range of applications. For example, ancient Greeks, Romans, and Egyptians used silver for a variety of medical applications<sup>1</sup> and as a food or water preservative.<sup>2</sup> In the form of nanoparticles (i.e., particles having sizes up to  $\sim 100$  nm), silver is extensively being employed as an effective antimicrobial agent,<sup>3</sup> as well as in applications including catalysis,<sup>4,5</sup> sensing and imaging,<sup>6,7</sup> as well as for synthesizing new electronic materials,<sup>8</sup> among others. Silver clusters containing up to tens of atoms have further extended the application of this noble metal in optoelectronics,<sup>9</sup> plasmonics,<sup>10</sup> biomedicine,<sup>11</sup> and DNA sequencing.<sup>12</sup>

Considering the high interest in silver clusters, developing synthesis processes with good scalability is highly important. In this respect, spark ablation<sup>13</sup> provides a versatile method for synthesizing metal-based clusters and nanoparticles, having a number of advantages, including good control over the size and composition of the resulting clusters/nanoparticles.<sup>13,14</sup> Typically, spark ablation is operated at atmospheric pressure with carrier gases that unavoidably contain trace amounts of impurities, including oxygen, that can affect the composition of the resulting clusters.

The stable geometries of pure silver clusters, including their ions, are among the most well-established.<sup>13,15–21</sup> For a period, it was believed that silver clusters did not react with  $\text{O}_2$ .<sup>22</sup> However, experimental evidence showed that they could be oxidized under certain conditions.<sup>15,18,23–31</sup> In light of that, a number of studies have explored the stabilities and geometries of the charged silver oxide clusters.<sup>18,23,27,28,31–34</sup> Schmidt et al.<sup>18</sup> have produced silver oxide clusters (i.e.,  $\text{Ag}_n\text{O}^+$  and  $\text{Ag}_n\text{O}_2^+$  with

$n = 1-9$ ) and observed that stabilities follow the magic numbers (i.e., shell closing at 2, 8, 20, 40, 58, etc., free electrons), whereas the most favored dissociation channel is the elimination of a silver monomer or dimer. They have also determined the minimum energy structures of these oxidized clusters by *ab initio* density functional theory (DFT) calculations using Perdew, Burk, and Ernzerhof (PBE) generalized gradient approximation (GGA) functionals<sup>35</sup> with a plane-wave basis function. In contrast to  $\text{Ag}_n^+$  clusters with  $n \leq 7$ , their oxidized products  $\text{Ag}_n\text{O}^+$  and  $\text{Ag}_n\text{O}_2^+$  adopt a 3D structure even for values of  $n$  as small as 3. Wang and Gong<sup>34</sup> also determined the minimum energy structures and stabilities of  $\text{Ag}_n\text{O}_m^+$  ( $n = 1-6$ ,  $m = 1-2$ ) clusters by the local spin density approximation (LSDA)<sup>36</sup> method using projector augmented-wave (PAW)<sup>37</sup> potentials. In general, their calculations corroborate those reported by Schmidt et al.<sup>18</sup>

The results of Schmidt et al. and Wang et al. are in contrast to independent calculations reported by Roithová et al.<sup>33</sup> and Flurer et al.<sup>23</sup> In the case of  $\text{Ag}_2\text{O}^+$ , for example, Roithová and co-worker<sup>33</sup> found the ground-state geometry to be almost linear ( $\angle\text{AgOAg} = 179.8^\circ$ ), whereas Schmidt et al.<sup>18</sup> and Wang et al.<sup>34</sup> reported a triangular geometry with  $\angle\text{AgOAg} = 149.0^\circ$  and  $138.1^\circ$ , respectively. Flurer and co-workers<sup>23</sup> also

Received: April 22, 2022

Revised: August 31, 2022

Published: September 13, 2022

determined a linear geometry, albeit using a less accurate Hartree–Fock (HF) self-consistent field (SCF) level of theory. Wang et al. found that the linear geometry is less stable and lies at least 0.03 eV above the energy of triangular geometry. It is interesting to note that the calculations reported in the literature so far have been performed within the HF or DFT formalism. As a result, and considering the contradicting calculations reported so far, it is of utmost importance to re-evaluate the ground-state geometries of the  $\text{Ag}_n\text{O}_m^+$  clusters with a more sophisticated electronic structure theory.

In addition to the information provided by electronic structure theory, determining the electrical mobility of the ionic clusters both theoretically and experimentally is highly useful for gaining insights into their size and morphology. The electrical mobility (a measure of drift velocity) at a particular pressure and temperature is inversely proportional to the average collision cross-section (CCS; a measure of size).<sup>38,39</sup> Jarrold and co-workers<sup>40,41</sup> have shown that the CCS can be calculated through quantum chemical considerations. Naturally, the accuracy of the calculated CCS depends on the geometry of the clusters, which can be determined by *ab initio* calculations, and consequently on the specific method employed. For the pure silver cluster cations ( $\text{Ag}_n^+$ ,  $n < 12$ ), Weis et al.<sup>17</sup> found that both experimentally measured and theoretically determined CCS values are in good agreement with each other, although significant discrepancies were reported for some other cases. More recently, Maisser et al. determined the electrical mobilities of both positively and negatively charged silver-based clusters having up to 25 Ag atoms.<sup>13</sup> The clusters were produced by spark ablation, and subsequently, their mobility was determined by a Differential Mobility Analyzer (DMA; ref 42) at atmospheric pressure. As stated, considering that carrier gases, even after high purification processing, can contain trace amounts of impurities, including oxygen, the resulting aerosol contains a high fraction of stable oxidized clusters produced by the etching effect.<sup>43</sup> Therefore, it is advantageous to reassess the broad electrical mobility spectra obtained for silver cluster cations by also adding their oxidized variants.

In this work, we theoretically determine the minimum energy structure, stabilization energy, and electrical mobility of  $\text{Ag}_n\text{O}_m^+$  clusters. We compare the calculated stabilization energies and the mobilities of the ionic clusters with experimentally determined mass and electrical mobility spectra, respectively. For the electronic energy calculations, we used a very accurate coupled cluster (CC) with single (S), double (D), and perturbative triple (T) excitation (CCSD(T)) level of theory.<sup>44–47</sup> Because the CCSD(T) method scales with the number of basis sets as  $O(N^7)$ <sup>48</sup> and, consequently, substantial computational costs are associated with very large systems, we have restricted our calculations to clusters with  $n = 1–4$  and  $m = 1–5$ . The rest of the paper is organized in three sections, with section 2 giving details of the computational methods used in this work, section 3 providing a discussion on the stable geometries, dissociation energies, and electrical mobilities of the  $\text{Ag}_n\text{O}_m^+$  clusters, and section 4 highlighting the most important conclusions.

## 2. COMPUTATIONAL DETAILS

**2.1. Electronic Structure Calculations.** We have used the Gaussian 16 package,<sup>49</sup> in combination with the isomer module of the ABCluster program,<sup>50–52</sup> to search systematically for the best candidate structures of  $\text{Ag}_n\text{O}_m^+$  clusters with  $n = 1–4$  and  $m = 1–5$ . The ABCluster estimates the potential energy of a

configuration and then constitutes a set of the best trial solutions by an efficient feedback-knowledge loop. Full dimensional geometry optimizations have been performed from this pool of structures at the M06<sup>53</sup> level of theory, which has been reported to produce electronic properties that are consistent with experimental observations for the charged silver clusters.<sup>21</sup>

A few of the low energy structures obtained at the M06 level are subsequently optimized at the CCSD level of theory<sup>44–46</sup> with a tighter energy convergence ( $2 \times 10^{-9}$  Hartree). Finally, single-point energy calculations on the geometries optimized by the CCSD method have been performed by the more accurate CCSD(T) theory<sup>47</sup> to account for the ground-state electronic energy. For the ground-state wave function that is essentially a single-reference character, the CCSD(T) method is often termed as the “gold standard” of quantum chemistry due to its ability to obtain accurate bond energies and molecular properties of reasonably large molecules.<sup>48</sup> Truhlar et al.<sup>19</sup> showed that the M06 method could accurately predict all low-energy isomers of charged silver clusters, whereas the differences of the relative energy are also in good agreement with the CCSD(T) calculations<sup>54</sup> (below approximately  $\pm 0.1$  eV). In this study, all isomers found in the M06 method that have energies below 1.0, 0.75, and 0.5 eV in comparison to the lowest energy isomer for  $n \leq 2, 3$ , and 4, respectively, are taken into consideration for the CCSD calculations. Harmonic frequency analysis has also been performed on all isomers to verify the local minima on the potential energy surface.

In this study, we calculated the two spin states for each cluster: i.e., singlet and triplet state for even numbers and doublet and quartet state for odd numbers of electrons. We have chosen the standard Dunning’s augmented correlation-consistent triple- $\zeta$  basis set (aug-cc-pVTZ) for the oxygen atoms (contracted to 5s4p3d2f),<sup>55,56</sup> and the cc-pVTZ basis set (contracted to 5s5p4d2f1g) with the inner core electrons described by Stuttgart/Köln energy consistent pseudopotential (ECP28MDF) for the silver atoms.<sup>57,58</sup>

The zero-point vibrational energy (ZPVE) corrected stabilization energy ( $\Delta E$ ) of the clusters were calculated with respect to the lowest energy dissociation channel  $\text{Ag}_n\text{O}_m^+ \rightarrow \text{Ag}_{n-x}\text{O}_{m-y}^+ + \text{Ag}_x\text{O}_y$  (i.e., the unimolecular dissociative reaction of the  $\text{Ag}_n\text{O}_m^+$  clusters absorbing least/releasing most energy) as<sup>18,34</sup>

$$\Delta E = E(\text{Ag}_{n-x}\text{O}_{m-y}^+) + E(\text{Ag}_x\text{O}_y) - E(\text{Ag}_n\text{O}_m^+) \quad (1)$$

where,  $E(\text{Ag}_{n-x}\text{O}_{m-y}^+)$ ,  $E(\text{Ag}_x\text{O}_y)$ , and  $E(\text{Ag}_n\text{O}_m^+)$  are the total energies of  $\text{Ag}_{n-x}\text{O}_{m-y}^+$ ,  $\text{Ag}_x\text{O}_y$ , and  $\text{Ag}_n\text{O}_m^+$  clusters, respectively. We should note that  $x$  and  $y$  can take any value from 0 to  $n$  and 0 to  $m$ , respectively, with the constraint that they cannot be both zero simultaneously.

**2.2. Collision Cross-Section and Electrical Mobility Calculation.** The CCS and electrical mobility of the lowest energy ionic structures were calculated by the MOBCAL code.<sup>40</sup> The electrical mobility  $Z$  of the ions were determined as<sup>40</sup>

$$Z = \frac{(18\pi)^{1/2}}{16} \left[ \frac{1}{m} + \frac{1}{m_B} \right]^{1/2} \frac{ze}{(k_B T)^{1/2} \Omega N} \quad (2)$$

Here,  $m$  and  $m_B$  are respectively the mass of the ion and carrier gas atom,  $z$  is the number of elementary charge ( $e$ ) carried by the ion,  $k_B$  is the Boltzmann constant,  $T$  is the effective temperature,  $N$  is the number density of the gas, and  $\Omega$  is the average CCS, which was calculated here by three different approaches: (i) the projection approximation (PA),<sup>59</sup> (ii) the exact hard-spheres

scattering (EHSS),<sup>41</sup> and (iii) the trajectory method (TM).<sup>40</sup> The hard-sphere radius  $r_{\text{hs}}$  and 12–6 Lennard-Jones parameters that are required for the calculation of the CCSs with the three methods mentioned above are provided in Table 1.

**Table 1.** Hard Sphere Radius ( $r_{\text{hs}}$ ; Å), 12-6 Lennard-Jones Parameters of Energy ( $\epsilon$ ; meV), and Van der Waals Distance ( $\sigma$ ; Å) for O and Ag Atoms

species	$r_{\text{hs}}$	12–6 Lennard-Jones parameters	
		$\epsilon$	$\sigma$
O	1.52 <sup>a</sup>	1.07 <sup>b</sup>	2.43 <sup>b</sup>
Ag	1.57 <sup>c</sup>	1.35 <sup>d</sup>	3.00 <sup>d</sup>

<sup>a</sup>Ref 60. <sup>b</sup>Ref 61. <sup>c</sup>Ref 17. <sup>d</sup>Ref 62.

It has been reported that, when used for mobility or CCS calculations, the chosen values of the parameters provided in Table 1 show good correspondence with the experimental results.<sup>17,61,62</sup> For example, Weis et al. found excellent agreement with experimental results when either the  $r_{\text{hs}}$  or the 12–6 Lennard-Jones parameters, as mentioned in Table 1, were used to calculate the CCS of pure cationic silver clusters<sup>17</sup> ( $\text{Ag}_n^+$  with  $n < 12$ ) or mixed silver–gold cation clusters<sup>62</sup> ( $\text{Ag}_m\text{Au}_n^+$  with  $m + n < 6$ ), respectively. On the other hand, the  $\epsilon$  and  $\sigma$  values of O atoms have been optimized by using drift-tube measurements of CCSs for oxygen-containing organic compounds.<sup>61</sup>

We have also performed preliminary calculations of the CCS and  $Z$  using the parameters in Table 1 and found good agreement with reported experimental values. For example, the

experimental CCS ( $32.5 \text{ \AA}^2$ ) of  $\text{Ag}_2^+$  measured by Weis et al.<sup>17</sup> is very close to the values calculated by the three methods (ranging between  $31.8$  and  $33.1 \text{ \AA}^2$ ). The experimentally determined electrical mobility of the  $\text{O}_2^+$  ion ( $21.8 \pm 1.7 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ )<sup>63</sup> is also in good agreement with calculated results ( $22.2$ – $23.3 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ ). Furthermore, we have analyzed the sensitivity of the mobility calculations with respect to the chosen values of the parameters and found that, for a 10% change in  $\epsilon$  and  $\sigma$ , there is a corresponding  $\sim 1\%$  and  $\sim 11\%$  deviation in the CCS values calculated by the TM method, as well as in the corresponding electrical mobilities. In contrast, the same change in the hard-sphere radius ( $r_{\text{hs}}$ ) parameter induces at least 18% deviation in the CCS values predicted by the PA and EHSS approaches.

We run  $5 \times 10^7$  classical trajectories for each TM simulation, with the charge distribution on each atomic center being determined by the Natural Population Analysis (NPA).<sup>64</sup> We should note here that NPA has been reported to have excellent numerical stability with respect to variations in basis set and method,<sup>65</sup> and good agreement with the empirical structure–function relationship.<sup>66</sup> Since the experimental mobility spectrum has been obtained using helium as the carrier gas,<sup>13</sup> for a direct comparison, the mobility calculations have been performed using the same gas having a polarizability of  $0.205 \text{ \AA}^3$ . We should note that all calculations have been performed at  $20 \text{ }^\circ\text{C}$  and 1 atm pressure.

### 3. RESULTS AND DISCUSSION

**3.1. Electronic Properties of the  $\text{Ag}_n\text{O}_m^+$  Clusters.** The ground-state structures of the  $\text{Ag}_n\text{O}_m^+$  clusters are illustrated in Figures 1–4, and the corresponding coordinates are provided in Tables S1–S20. In general, as the size of the clusters increases,

**Figure 1.** Ground-state structures of the  $\text{AgO}_m^+$  clusters, optimized by the CCSD method, where  $m = 1$ – $5$ . Red spheres denote oxygen atoms, and the cyan sphere indicates the silver atom of the clusters. Bond lengths (black fonts) and angles (blue fonts) are given in Å and degrees, respectively. Spin multiplicities are provided in parentheses.

**Table 2.** Summary of the CCSD(T) and Electrical Mobility Calculations on the Ground State of  $\text{AgO}_m^+$ ,  $\text{Ag}_2\text{O}_m^+$ ,  $\text{Ag}_3\text{O}_m^+$ , and  $\text{Ag}_4\text{O}_m^+$  Clusters, Where,  $m = 1-5^a$

<sup>a</sup> $2S + 1$ : Spin multiplicity. PG: Point group symmetry.  $\Delta E$ : Zero-point vibrational energy (ZPVE) corrected stabilization energy (in eV) with respect to the lowest energy dissociation channel.  $\mu$ : Dipole moment at the center of mass (in Debye). VEA: Vertical electron affinity (in eV).  $\Omega$ : Collision cross-section (in  $\text{\AA}^2$ ).  $Z^{-1}$ : Inverse electrical mobility (in  $\text{V s m}^{-2}$ ). PA: Projection approximation method. EHSS: Exact hard spheres scattering method. TM: Trajectory method.

**Figure 2.** Ground-state structures of the  $\text{Ag}_2\text{O}_m^+$  clusters optimized by the CCSD method, where  $m = 1-5$ . Red spheres denote oxygen atoms, and cyan spheres indicate silver atoms. Bond lengths (black fonts) and angles (blue fonts) are given in  $\text{\AA}$  and degrees, respectively. Spin multiplicities are provided in parentheses.

the ground state tends to have a greater spin multiplicity; i.e., triplet (for an even number of electrons) and quartet (for an odd

number of electrons) spin states are favored over singlet and doublet states (see Table 2). More specifically, for  $\text{AgO}_m^+$  and

**Figure 3.** Ground-state structures of the  $\text{Ag}_3\text{O}_m^+$  clusters optimized by the CCSD method, where  $m = 1-5$ . Red spheres denote oxygen atoms, and cyan spheres indicate silver atoms. Bond lengths (black fonts) and angles (blue fonts) are given in ångstroms and degrees, respectively. Spin multiplicities are provided in parentheses.

**Figure 4.** Ground-state structures of the  $\text{Ag}_4\text{O}_m^+$  clusters optimized by the CCSD method, where  $m = 1-5$ . Red spheres denote oxygen atoms, and cyan spheres indicate silver atoms. Bond lengths (black fonts) and angles (blue fonts) are given in ångstroms and degrees, respectively. Spin multiplicities are provided in parentheses.

$\text{Ag}_3\text{O}_m^+$ , only one singlet state has been found in each series. On the other hand, the two smallest clusters in the series of  $\text{Ag}_2\text{O}_m^+$  and  $\text{Ag}_4\text{O}_m^+$  are doublets.

The geometry of the clusters in their ground state is planar if the total number of atoms in the cluster is equal to or less than four. The remaining clusters adopt a 3D structure. This is markedly different to the results reported by Roithová et al.<sup>33</sup> and Wang et al.,<sup>34</sup> where  $\text{Ag}_n\text{O}_m^+$  clusters are 3D starting from tetra-atomic systems.

Interestingly, when  $m \geq 2$ , the  $\text{Ag}_n\text{O}_m^+$  clusters have a terminal  $\text{O}_2$  fragment attached to an Ag atom. The O–O bond length in these clusters has a length of 1.20 Å, which is almost equal to that of the free  $\text{O}_2$  molecule (1.21 Å).<sup>67</sup> In these clusters, the Ag–O bond lengths are elongated (2.41–2.57 Å) compared to those of the pure AgO molecule (2.0 Å).<sup>67</sup> These results suggest that  $\text{O}_2$  is weakly bonded to the  $\text{Ag}_n\text{O}_{m-2}^+$  clusters and can, therefore, dissociate more easily, as discussed further below. A consequence of the weakly bounded  $\text{O}_2$  is that the minimum energy geometry of a particular series of  $\text{Ag}_n\text{O}_m^+$  is similar to that of the  $\text{Ag}_n\text{O}_{m-2}^+$  clusters, with the exception of the case where an additional  $\text{O}_2$  is attached to a terminal Ag atom. These observations are consistent for all  $\text{Ag}_n\text{O}_m^+$  clusters studied in this work when the number of Ag atoms in the cluster remains the same. However, there are some notable deviations when the two oxygen atoms are bonded with two separate Ag atoms, and there is no  $\text{O}_2$  moiety at the extremity ( $\text{Ag}_2\text{O}_2^+$  and  $\text{Ag}_4\text{O}_2^+$ ; see Figures 2b and 4b). In these two cases, the O–O distance is slightly elongated (ranging from 1.32 to 1.34 Å), and the Ag–O distance is shortened (from 2.19 to 2.23 Å) when compared to other clusters with  $m \geq 2$ .

Our results also show that the Ag–O bond length in the  $\text{AgO}^+$  cluster is 2.34 Å (Figure 1a) but increases to 2.52 Å for  $\text{AgO}_2^+$  (Figure 1b). In  $\text{AgO}_3^+$ , the Ag–O bonds are further elongated to 2.60–2.61 Å, while the distance in the O–O bond increases compared to that of  $\text{AgO}_2^+$  (from 1.20 to 1.25 Å, respectively) (Figure 1c). We note that  $\text{AgO}_3^+$  has a planar geometry and only a slight difference in the two Ag–O bond lengths, thus deviating from a  $C_{2v}$  point group symmetry. An incremental difference in the Ag–O bond length between  $\text{Ag}_2\text{O}^+$  (Figure 2a) and  $\text{Ag}_2\text{O}_2^+$  (Figure 2b) (2.15 and 2.21 Å, respectively) is also observed. With the exception of the linear  $\text{AgO}^+$  ion, the most symmetric structure (in terms of the total number of symmetry operations) found in this study is that of the  $\text{Ag}_3\text{O}^+$  cluster, which has a trigonal planar geometry with a short AgO bond length (2.09 Å; see Figure 3a). On the other hand, the  $\text{Ag}_3\text{O}_2^+$  cluster can be considered as Ag atoms sitting at the corners of an equilateral triangle having sides with a length of  $\sim 2.8$  Å, with one of them being attached to an  $\text{O}_2$  molecule (Figure 3b). Interestingly, the positively charged pure  $\text{Ag}_3^+$  ion is also an equilateral triangle with similar side lengths, as reported by McKee and co-workers.<sup>21</sup> Therefore, the ground state of the  $\text{Ag}_3\text{O}_2^+$  cluster can be considered as the combination of  $\text{Ag}_3^+$  and  $\text{O}_2$  fragments in close proximity. Similarly, the  $\text{Ag}_4\text{O}_2^+$  cluster (Figure 4b) has a structure similar to that of  $\text{Ag}_3\text{O}_2^+$ , with the fourth Ag atom attached to the terminal O atom of the  $\text{O}_2$  moiety.

Some discrepancies are observed by comparing the geometries determined in our study with those already reported in the literature. Most notably, we find that the ground state of the  $\text{Ag}_2\text{O}^+$  cluster (Figure 2a) is almost linear with  $\angle\text{AgOAg} = 172.2^\circ$ , which is in line with the results reported by Roithová et al.<sup>33</sup> but in contrast with those provided by Schmidt et al.<sup>18</sup> and Wang et al.<sup>34</sup> The energy of this structure is at least 0.18 eV (0.13 eV for M06 calculations in this work) lower compared to that of

the bent structure as obtained in the two latter studies. Indeed, we find that both PBE and LSDA functionals (with the same basis set as employed in this study) refer to the ground state having a bent geometry, which has respectively at least 0.07 and 0.28 eV lower energy compared to that of the linear geometry. We find that the Ag–O bond length is also marginally longer (2.15 Å) than those previously reported by Schmidt et al. and Wang et al. (2.09 and 1.98 Å, respectively).

Similarly, Schmidt et al. and Wang et al. reported that the ground state of  $\text{Ag}_3\text{O}^+$  (Figure 3a) and  $\text{Ag}_4\text{O}^+$  (Figure 4a) clusters have respectively a tetrahedron-like and capped tetrahedron geometry, both belonging to the  $C_{3v}$  point group symmetry. In contrast, we find that the ground state of these clusters belongs to the  $D_{3h}$  ( $\text{Ag}_3\text{O}^+$ ) and  $C_1$  ( $\text{Ag}_4\text{O}^+$ ) symmetric configurations, which have 0.40 and 0.15 eV, respectively, lower energy than the previously reported  $C_{3v}$  geometries. We should note, however, that the  $\text{Ag}_4\text{O}^+$  cluster marginally deviates by an Ag–O bond length of  $\pm 0.07$  Å (see Figure 4a) from having a pure tetrahedral geometry. Additional geometrical discrepancies are also seen for the  $\text{Ag}_2\text{O}_2^+$  (Figure 2b) and  $\text{Ag}_4\text{O}_2^+$  (Figure 4b) clusters. These discrepancies may stem from the difference in the accuracy of the *ab initio* methods employed, the convergence criteria, or the total number of candidate structures and their geometries considered in the respective studies. Nevertheless, we have found good agreement with the previous reports for a few species, including the  $\text{AgO}_2^+$  (Figure 1b) and  $\text{Ag}_3\text{O}_2^+$  (Figure 3b) clusters.

In addition to the ground-state geometries, we have also determined other properties of the oxidized silver clusters, such as the dipole moment  $\mu$  and the vertical electron affinity (VEA). The calculated values are provided in Table 2. Since the dipole moment of an electrically charged species is not invariant under the choices of the coordinate frame, it has been calculated at the center of mass of the cluster. The direction of the dipole vectors is fully consistent with the partial charges determined by the NPA method; i.e. they point toward the plane containing the positively charged Ag atom(s) (see SI for charges calculated by the NPA method on the  $\text{Ag}_n\text{O}_m^+$  clusters). As expected, some symmetric structures, such as those of  $\text{Ag}_2\text{O}_2^+$  (Figure 2b) and  $\text{Ag}_3\text{O}^+$  (Figure 3a), have zero net dipole moments. The  $\text{Ag}_4\text{O}_m^+$  clusters appear to have higher dipole moments than other  $\text{Ag}_n\text{O}_m^+$  series, most likely due to a greater number of partially charged Ag atoms located away from the center of mass (Figure 4a). Finally, the VEA values can be distinctly categorized with respect to the value of  $n$ . For  $n = 1–3$ , the VEA values decrease as  $n$  increases. For example, the VEAs span from 6.9 to 7.4 eV for the  $\text{AgO}_m^+$  series but decrease to the range of 5.8–6.2 eV for the  $\text{Ag}_2\text{O}_m^+$  clusters and to 5.1–5.5 eV for the  $\text{Ag}_3\text{O}_m^+$ . Interestingly, the VEAs of the  $\text{Ag}_4\text{O}_m^+$  clusters are spread over a rather broad range: i.e., from 6.0 eV for  $\text{Ag}_4\text{O}_3^+$  to 3.0 eV for  $\text{Ag}_4\text{O}_5^+$ .

**3.2. Stabilization Energies of the  $\text{Ag}_n\text{O}_m^+$  Clusters.** The ZPVE corrected  $\Delta E$  of the  $\text{Ag}_n\text{O}_m^+$  clusters are provided in Table 2 and shown in Figure 5a. Evidently, the stabilization of the clusters with  $m \geq 2$  is comparatively lower than those with  $m = 1$ . These clusters preferably dissociate by eliminating a weakly bonded oxygen molecule. The calculated  $\Delta E$  values for the clusters with  $m \geq 2$  range from approx.  $-0.27$  to 0.28 eV, suggesting that some clusters are unstable ( $\Delta E \leq 0$ ; viz.,  $\text{AgO}_4^+$ ,  $\text{Ag}_3\text{O}_4^+$ , and  $\text{Ag}_3\text{O}_5^+$ ) and will promptly dissociate. The  $\Delta E$  values of most of the remaining  $\text{Ag}_n\text{O}_m^+$  clusters (with  $m \geq 2$ ) have a value of  $\sim 0.2$  eV. One exception to this generalization is the  $\text{AgO}_3^+$  cluster, for which the calculated stabilization energy is significantly greater than those of other clusters ( $\sim 0.8$  eV). We

**Figure 5.** (a) Stabilization energies,  $\Delta E$ , of the  $\text{Ag}_n\text{O}_m^+$  clusters ( $n = 1-4$  and  $m = 0-5$ ) with respect to the lowest energy dissociation channel. The  $\Delta E$  values are calculated by the CCSD(T) method. (b) Mass spectra of atomic silver clusters produced by atmospheric-pressure spark ablation provided by Maisser et al. (ref 43). The abscissa of panel (a) has the same value, unit, and label as that of panel (b).

should highlight here that in  $\text{AgO}_3^+$ , the Ag atom is directly bonded with two O atoms, and the third O atom is centrally bonded with those (see Figure 1c). We determine that this ion will most readily dissociate not through the release of  $\text{O}_2$  but of an ozone molecule and a silver cation  $\text{Ag}^+$ . Dissociation of  $\text{AgO}_3^+$  to yield  $\text{AgO}^+ + \text{O}_2$  would require surmounting a potential energy barrier of around 1.1 eV. The  $\Delta E$  values for  $\text{Ag}_n\text{O}_2^+$  clusters calculated in this work are considerably smaller (i.e., less stable clusters) than the  $\text{O}_2$  binding energy reported by Wang et al.<sup>34</sup> For example, we estimate that the binding energy of  $\text{O}_2$  on  $\text{Ag}_2\text{O}_2^+$  is 0.2 eV, whereas Wang and co-workers report a value of 1 eV.

With the exception of  $\text{AgO}_3^+$ , the stabilization energy of the  $\text{Ag}_n\text{O}^+$  clusters is, in general, far larger than those of the clusters with  $m \geq 2$  (see Table 2). This finding is consistent with those reported by Schmidt et al.<sup>68</sup> in the condensed phase, who showed that the detection intensity of  $\text{Ag}_n\text{O}^+$  clusters was substantially higher than that of their  $\text{Ag}_n\text{O}_2^+$  counterparts.  $\Delta E$  of  $\text{Ag}_2\text{O}^+$  and  $\text{Ag}_3\text{O}^+$  have similar values ( $\sim 2.8$  eV) and are notably larger than those of  $\text{AgO}^+$  (0.5 eV) and  $\text{Ag}_4\text{O}^+$  (1.2 eV), in agreement with previous DFT level calculations reported by Schmidt and co-workers<sup>18</sup> and Roithová et al.<sup>33</sup> The enhanced stabilization energy of the  $\text{Ag}_2\text{O}^+$  and  $\text{Ag}_3\text{O}^+$  clusters can seemingly be attributed to a stronger Coulombic interaction between partially positive Ag atoms surrounding the negatively charged O atoms at a shorter distance (cf., Figure S1 for charges calculated by the NPA method for the  $\text{Ag}_n\text{O}^+$  clusters). Interestingly, in the equilibrium geometry of  $\text{AgO}^+$ , there is no net charge on the O atom. This suggests that there is no effective Ag to O charge transfer in  $\text{AgO}^+$ , in contrast to the neutral AgO cluster, whereas the potential energy curve of  $\text{AgO}^+$  has a shallow well of  $\sim 0.5$  eV (see Figure S2). The bond dissociation energy of  $\text{Ag}^+-\text{O}$  reported here is somewhat smaller than the purely speculative experimental value of  $1.23 \pm 0.05$  eV,<sup>24</sup> or the DFT calculated values reported by Wang and co-workers,<sup>34</sup> but have a better agreement with those provided by Schmidt ( $\approx 0.8$  eV). For  $n = 2$  and 4, the lowest energy dissociation channel leads to the formation of a silver cluster cation and a single O atom ( $\text{Ag}_n\text{O}^+ \rightarrow \text{Ag}_n^+ + \text{O}$ ). In contrast,  $\text{Ag}_3\text{O}^+$  would preferably

dissociate into  $\text{Ag}_2\text{O}^+ + \text{Ag}$ , which has a 0.2 eV lower energy than the  $\text{Ag}_3^+ + \text{O}$  channel.

Figure 5a shows the stabilization energies of the  $\text{Ag}_n\text{O}_m^+$  clusters predicted in this work, whereas Figure 5b provides the mass spectra (MS) of Ag-based cations reported by Maisser et al.<sup>43</sup> As the signal strength in the experimentally determined MS can be a measure of relative abundances and consequently related to the relative stabilization energy of the clusters, we can qualitatively compare them with the theoretically determined stabilization energies. In all cases, the mass spectrometry signals of  $\text{Ag}_n\text{O}_m^+$  clusters for  $n > 1$  and  $m \geq 2$  are weaker than those obtained for  $m = 0$  or 1. These signals progressively become weaker with increasing  $m$ . This is, in general, in agreement with the calculated stabilization energies of the  $\text{Ag}_n\text{O}_m^+$  clusters and the experimental validation by Schmidt et al.<sup>18</sup> Similarly,  $\text{AgO}_m^+$  clusters with  $m = 1, 2$ , and 3 have comparable signal strengths in the MS, in accordance with the corresponding  $\Delta E$  values. By comparing the stabilization energies of the pure  $\text{Ag}_n^+$  clusters (i.e.,  $\text{Ag}_2^+$ ,  $\text{Ag}_3^+$ , and  $\text{Ag}_4^+$ ) with respect to the lowest energy dissociation channel ( $\text{Ag}_{n-1}^+ + \text{Ag}$  for even  $n$ , and  $\text{Ag}_{n-1} + \text{Ag}^+$  for odd  $n$ ) with those obtained for  $\text{Ag}_n\text{O}^+$  ( $n = 2-4$ ), we can interpret the remaining peaks of the MS. For instance, the  $\Delta E$  of  $\text{Ag}_2\text{O}^+$  is much greater than that of the  $\text{Ag}_2^+$  ion (2.82 and 1.48 eV, respectively), which can explain the stronger signal in the case of the oxidized species. On the other hand, the difference in  $\Delta E$  between  $\text{Ag}_3\text{O}^+$  and  $\text{Ag}_3^+$  (2.86 and 2.57 eV, respectively) or  $\text{Ag}_4\text{O}^+$  and  $\text{Ag}_4^+$  (1.16 and 1.00 eV, respectively) pairs are very small and consequently can explain the similar magnitudes of the respective signals in the MS. These comparisons show that as the silver clusters increase in size, they have a smaller tendency to react with oxygen. Formation of predominantly pure silver is to be expected for clusters with  $n \geq 10$ . It should be noted that the  $\Delta E$  values of the pure  $\text{Ag}_n^+$  clusters have also been determined at the CCSD(T) theory with ZPVE correction. Despite the excellent qualitative agreement between measurements and calculations, one should also consider that the MS have contributions from hydroxy silver cluster cations,  $\text{Ag}_n\text{OH}_m^+$ , as shown by Maisser et al.<sup>43</sup> To properly interpret the experimental MS, one would need to estimate the stabilities of the  $\text{Ag}_n\text{OH}_m^+$  clusters and additionally conduct kinetic studies on pure, oxygenated, and hydroxyoxygenated silver cluster cations in order to determine their relative abundances. This, however, is beyond the scope of this study.

**3.3. Collision Cross Sections and Electrical Mobilities of the  $\text{Ag}_n\text{O}_m^+$  Clusters.** The average CCSs for the  $\text{Ag}_n\text{O}_m^+$  clusters calculated by the PA, EHSS, and TM methods are provided in Table 2. In the remainder of this article, we specifically analyze results obtained by the TM approach as this has been reported to provide the most accurate results among the three methods and, most importantly, because it considers the long-range interactions between the ion and the buffer gas.<sup>40</sup> As the CCS is essentially a measure of cluster size, it increases as the number of oxygen atoms in a family of  $\text{Ag}_n\text{O}_m^+$  increases. One deviation from this generalization is observed for the  $\text{Ag}_4\text{O}_4^+$  cluster, which has a smaller CCS value than its  $\text{Ag}_4\text{O}_3^+$  counterpart that has one oxygen atom less (57.96 and 59.66 Å<sup>2</sup>, respectively). This anomaly can be explained by carefully inspecting the corresponding optimized geometries of the  $\text{Ag}_4\text{O}_3^+$  and  $\text{Ag}_4\text{O}_4^+$  ions. As already shown in Figure 4d, the ground state of  $\text{Ag}_4\text{O}_4^+$  is a compact cage-like structure with a total molecular area of 47.30 Å<sup>2</sup>, whereas  $\text{Ag}_4\text{O}_3^+$  (Figure 4c) has a more spread-out geometry and an increased molecular area (50.76 Å<sup>2</sup>).

Figure 6 shows the experimentally determined inverse mobility  $Z^{-1}$  spectrum measured by Maisser et al.,<sup>13</sup> where

**Figure 6.** Inverse electrical mobility,  $Z^{-1}$ , (in  $\text{V s m}^{-2}$ ) of  $\text{Ag}_n\text{O}_m^+$  clusters ( $n = 1-4$ ;  $m = 1-5$ ) and  $\text{Ag}_n^+$  clusters ( $n = 2-9$ ) in He calculated at  $20^\circ\text{C}$  and 1 atm.  $Z^{-1}$  values of  $\text{Ag}_n\text{O}_m^+$  clusters have been calculated by the trajectory method (TM), and for  $\text{Ag}_n^+$ , the clusters are based on the experimental collision cross sections reported in the literature (ref 17). They are both labeled as vertical lines on the experimental mobility spectrum provided by Maisser et al. (solid red lines, ref 13).

respective values of the oxidized and pure (the latter taken from ref 17) silver cluster cations are also labeled. The calculated values of  $Z^{-1}$  are also provided in Table 2. We should note that the  $Z^{-1}$  values for  $\text{Ag}_n^+$  clusters are marginally smaller than those provided by Maisser et al.<sup>13</sup> because they account for particularities in the calibration procedure used in the experiments. Similarly to the CCS,  $Z^{-1}$  increases with  $m$  for a particular series of  $\text{Ag}_n\text{O}_m^+$  clusters, except for  $\text{Ag}_4\text{O}_4^+$  due to its smaller size compared to  $\text{Ag}_4\text{O}_3^+$  as discussed in the previous paragraph.

A number of peaks and troughs that were previously unassigned in the experimental electrical mobility spectrum can now be labeled as belonging to a family of cationic clusters. For example, in the case of  $\text{Ag}_2\text{O}_2^+$ , the inverse mobility that coincides with the first experimental peak at  $Z^{-1} = 570 \text{ V s m}^{-2}$  appears alongside the signal corresponding to the  $\text{Ag}_2^+$  cluster. Similarly, the most prominent peak at  $Z^{-1} \approx 700 \text{ V s m}^{-2}$  has contributions from both  $\text{Ag}_3^+$  and  $\text{Ag}_2\text{O}_2^+$ . The following two peaks at larger  $Z^{-1}$  values of around 870 and 1000  $\text{V s m}^{-2}$  that are also labeled, respectively, contain the family of  $\text{Ag}_4\text{O}_m^+$  ( $m = 1-4$ ) and the  $\text{AgO}_4^+$  clusters. Likewise, the troughs appearing around 800, 950, and 1100  $\text{V s m}^{-2}$  correspond to  $\text{Ag}_3\text{O}^+$  and  $\text{Ag}_2\text{O}_3^+$ ,  $\text{Ag}_3\text{O}_3^+$ , and  $\text{Ag}_2\text{O}_5^+$ , and  $\text{Ag}_3\text{O}_5^+$  clusters, respectively.

It is evident that the relative abundances of the  $\text{Ag}_n\text{O}_m^+$  clusters labeled on the experimental electrical mobility spectrum do not precisely match the calculated stabilization energies, contradicting the comparison with the reported MS discussed in the previous section. This is particularly true for the  $\text{Ag}_3\text{O}^+$  cluster. The stabilization energy of  $\text{Ag}_3\text{O}^+$  is 2.86 eV exhibiting the highest  $\Delta E$  value compared to the rest of the species investigated in this work, corroborating the strong signal in the MS reported by Maisser et al.<sup>43</sup> However,  $\text{Ag}_3\text{O}^+$  falls at a trough in the experimentally determined electrical mobility spectrum,

which may suggest that the ground state of  $\text{Ag}_3\text{O}^+$  would dissociate rapidly. This seemingly contradictory observation could be the result of one or a combination of the following factors. First, there could be isomers of  $\text{Ag}_3\text{O}^+$  that are sufficiently long-lived and have ion mobilities that fall under the adjacent peaks in the mobility spectrum. We have calculated that the tetrahedron-like structure reported by Schmidt et al.<sup>18</sup> and Wang et al.,<sup>34</sup> and the first triplet state of  $\text{Ag}_3\text{O}^+$  (cf., Figure S3) have a  $Z^{-1}$  value of  $744 \text{ V s m}^{-2}$ . This value, which is lower than that estimated for the  $D_{3h}$  structure (corresponding to  $773 \text{ V s m}^{-2}$ ) may signify a greater abundance of these two isomers. Second, it has been reported that for small and medium ions, when optimized Lennard-Jones parameters are used in the computation of CCS, the accuracy of the TM method of the MOBCAL code usually falls within 4% of the experimental value.<sup>61,69</sup> Due to the lack of experimental data on either CCS or electrical mobility of silver oxide cations, we have utilized nonoptimized Lennard-Jones parameters in this study. Lastly, the signals in both the mass and the electrical mobility spectra are affected by the penetration of the instruments, which can well depend on the mass and mobility of the measured clusters, respectively.

To further investigate the agreement between the theoretical calculations carried out here and the respective mobility measurements reported by Maisser et al.,<sup>13</sup> we compare the predicted mobility distributions determined from the signal strength of the MS of ref 43 (cf., Figure S4). Evidently, there is a good agreement between the measured and the predicted inverse mobility spectrum. However, few notable differences are also observed since the electrical mobility and the mass spectra measurements have been performed separately, and hence, important differences in the composition of the resulting clusters cannot be ruled out. The most prominent discrepancy arises for the  $\text{Ag}_2^+$  cluster as its relative abundance is 0.9 au in the predicted mobility spectrum and 0.1 a.u. in the experimental spectrum. Remarkably,  $\text{Ag}_3\text{O}^+$  falls at a peak in the predicted mobility spectrum since it is accompanied by a strong signal in the corresponding MS. Unsurprisingly,  $\text{Ag}_3^+$ ,  $\text{Ag}_3\text{O}^+$ ,  $\text{Ag}_4^+$ , and  $\text{Ag}_4\text{O}^+$  clusters have similar relative abundances and signal strengths in the predicted mobility and the experimental spectra.

The weakening signal with growing cluster size (Figure 6) can also be connected to experimental artifacts. First, the transmission of the clusters through the mass spectrometer is mass-dependent and, in principle, decreases with increasing mass. In addition, clusters produced by spark ablation typically have a log-normal mobility/size distribution,<sup>43</sup> which also leads to a size-dependent signal of the clusters that can vary with the operating parameters of their production during the experiments. Finally, we should stress again that the Ag-based clusters produced during the experiments contain a high fraction of hydroxyls, resulting to species that can be more stable than their  $\text{Ag}_n\text{O}_m^+$  cluster counterparts. To make a quantitative comparison between theory and experiment, we need to consider those clusters as well as their mass/size-dependent penetrations in the MS measurements.

The deviation in the ion mobilities between the pure  $\text{Ag}_n^+$  cluster and its oxidized counterparts having the same number of silver atoms  $n$  can give valuable insights into the amount of oxidation, i.e., the total number of O atoms, in the cluster. Figure 7 shows the difference in inverse mobility  $Z^{-1}$  between pure  $\text{Ag}_n^+$  clusters with their oxygenated counterparts,  $\text{Ag}_n\text{O}_m^+$  for a particular value of  $n$  against  $m$ . Naturally, with increasing the

**Figure 7.** Difference in inverse electrical mobility,  $\Delta Z^{-1}$ , (in  $\text{V s m}^{-2}$ ) between (a)  $\text{Ag}^+$  and  $\text{AgO}_m^+$ , (b)  $\text{Ag}_2^+$  and  $\text{Ag}_2\text{O}_m^+$ , (c)  $\text{Ag}_3^+$  and  $\text{Ag}_3\text{O}_m^+$ , and (d)  $\text{Ag}_4^+$  and  $\text{Ag}_4\text{O}_m^+$ . Here,  $m = 1-5$ .  $Z^{-1}$  values of  $\text{Ag}_n\text{O}_m^+$  clusters have been calculated by the trajectory method (TM), and for  $\text{Ag}_n^+$ , the clusters are based on the experimental collision cross sections reported in the literature (ref 17).

number of oxygen atoms in the cluster,  $\Delta Z^{-1}$  increases as a result of the larger cluster size, except for the  $\text{Ag}_4\text{O}_4^+$  cluster.

The large difference in the  $\Delta Z^{-1}$  values between  $\text{Ag}_n^+$  and  $\text{Ag}_n\text{O}_m^+$  clusters can be explained by inspecting their respective ground-state geometries. For example,  $\text{Ag}_2\text{O}^+$ ,  $\text{Ag}_3\text{O}^+$ , and  $\text{Ag}_4\text{O}^+$  can be considered as structures in which an oxygen atom is placed at the center of pure  $\text{Ag}_2^+$ ,  $\text{Ag}_3^+$ , and  $\text{Ag}_4^+$  clusters, respectively (see Figure S5). This leads to an increased Ag–Ag bond length in the oxidized clusters compared to their pure counterparts (by 0.74–1.45 Å) and, in general, a larger cluster size. Since the significant contribution to the electrical mobility originates from the larger Ag atoms, it is not surprising that adding an O atom has a much smaller effect on the electrical mobility than adding an Ag atom. The deviation of the mobility of the  $\text{Ag}_n\text{O}_m^+$  species from their pure counterparts is high enough to be resolved by mobility analysis reported by Maisser et al.,<sup>13</sup> as this ranges from 24 to 160  $\text{V}^{-1} \text{s}^{-1} \text{cm}^2$  depending on the number of O atoms the clusters can contain for our study. Since the mobilities of some oxygenated species are very close to those of the pure clusters, and also among themselves, two or more species can correspond to each peak in the mobility spectrum obtained from low resolution DMA, as shown in Figure 6. For example,  $\text{Ag}_3\text{O}_4^+$  has a  $Z^{-1}$  value of 994.64  $\text{V s m}^{-2}$ , which is very close to the respective value calculated for  $\text{Ag}_4\text{O}_4^+$  (995.65  $\text{V s m}^{-2}$ ). Similarly,  $\text{Ag}_4\text{O}_5^+$  and  $\text{Ag}_5^+$  have comparable  $Z^{-1}$  values ( $\sim 1190 \text{ V s m}^{-2}$ ). In order to better resolve different oxidized species and have a more rigorous comparison with the theoretical results, one can combine mobility classification with mass spectrometry that can give further insights into the relationship between cluster mobility, mass, sizes, and stability.<sup>70,71</sup>

## 4. CONCLUSIONS

We have calculated the minimum energy structures, stabilization energy, electrical mobilities and various electronic properties of  $\text{Ag}_n\text{O}_m^+$  clusters ( $n = 1-4$ ;  $m = 1-5$ ) using a rigorous *ab initio* method. Geometry optimizations of the  $\text{Ag}_n\text{O}_m^+$  clusters have been performed at the CCSD level of theory, while single-point energies are determined by additionally incorporating the triples correction to the CCSD method (CCSD(T)). We find that the ground state of the larger cations tends to have a greater

multiplicity. In general, the ground state geometry of the  $\text{Ag}_n\text{O}_m^+$  clusters is similar to those of the  $\text{Ag}_n\text{O}_{m-2}^+$  clusters, with an additional  $\text{O}_2$  attached at their extremity, although there are some exceptions to this rule (e.g.,  $\text{Ag}_2\text{O}_2^+$  and  $\text{Ag}_4\text{O}_2^+$ ). The  $\text{Ag}_n\text{O}^+$  clusters adopt a geometry that inherits higher symmetry than other clusters and also has greater stabilization energy with respect to the lowest energy dissociation channel. This is apparently due to a strong Coulombic attraction between positively charged Ag atoms and a negatively charged O atom. On the other hand,  $\text{Ag}_n\text{O}_m^+$  clusters with  $m \geq 2$  are less stable due to the easy elimination of an  $\text{O}_2$  molecule attached to a terminal Ag atom, signaling a higher inertness of the silver clusters toward oxygen. We expect that this is a general feature and that larger clusters also split off  $\text{O}_2$ . Under this hypothesis and considering that even the bulk stable  $\text{Ag}_2\text{O}$  decomposes when heated,<sup>72</sup> it is well possible that silver oxide clusters produced by spark ablation (or other similar aerosol-based techniques) at atmospheric pressure can be reduced by heating their carrier gas, leading to an effective yet cost-effective way of producing pure silver clusters.

When comparing the structures of the oxidized silver clusters determined in this work with those previously obtained by DFT calculations, we find a number of disparities, e.g., in the case of the  $\text{Ag}_2\text{O}^+$  cluster. Through more rigorous computations, we find that the ground-state structure of  $\text{Ag}_2\text{O}^+$  is almost linear, in contrast to the bent geometry reported previously. Despite these discrepancies, however, the good qualitative agreement with experimentally determined mass spectra<sup>43</sup> builds trust in the *ab initio* calculations carried-out in this work.

The collision cross-section (CCS) and electrical mobilities of the  $\text{Ag}_n\text{O}_m^+$  clusters have also been calculated and labeled on a measured spectrum of silver-based atomic clusters produced by spark ablation at atmospheric pressure.<sup>13</sup> This comparison provides further insights into the species that can contribute to each peak of the measured mobility spectrum and verify the calculations that depend on the estimated structure of different clusters. Finally, estimated deviations in the ion mobilities of the pure silver cluster cations from their oxidized counterparts indicate that the resolving power of the measured mobility spectrum is high enough to distinguish between clusters having a different number of Ag atoms but not between clusters having the same number of Ag atoms and a different number of oxygen atoms since they appear in the same region of the mobility spectrum and consequently a peak or a trough may be the result of the presence or absence of more than one species. This limitation can be overcome by using accurate quantum chemical calculations or Differential Mobility Analysis-Mass Spectrometry (DMA-MS) in the future.

## Notes

The authors declare no competing financial interest.

## ACKNOWLEDGMENTS

The authors acknowledge the financial support of the European Regional Development Fund and the Republic of Cyprus through the Research Promotion Foundation NANO<sup>2</sup>LAB Project INFRASTRUCTURES/1216/0070. This research was also supported by the EMME-CARE project that has received funding from the European Union's Horizon 2020 Research and Innovation Program, under Grant Agreement No. 856612, as well as matching cofunding by the Government of the Republic of Cyprus. The authors thank the AMD EPYC High Performance Computing Facility of The Cyprus Institute for computational resources.
