15 **Abstract**

16 Enhanced *in situ* biodenitrification (EIB) is a feasible technology to clean nitrate-polluted
17 groundwater and reach drinking water standards. Aimed at enabling a better monitoring and
18 management of the technology at the field scale, we developed a two-dimensional reactive
19 transport model (RTM) of a cross section (26.5 x 4 m) of a fractured aquifer composed of marls
20 involving both biogeochemical processes and associated isotope fractionation. The RTM was
21 based on the upscaling of a previously developed batch-scale model and on a flow model that
22 was constructed and calibrated on *in situ* pumping and tracer tests. The RTM was validated
23 using the experimental data provided by Vidal-Gavilan et al. (2013). The model considers
24 several processes including (i) exogenous and endogenous microbial nitrate and sulfate
25 respiration coupled to ethanol oxidation and linked to microbial growth and decay, and (ii)
26 geochemical interactions (dissolution/precipitation of calcite), and (iii) isotopic fractionation of
27 the reaction network ($^{15}\text{N-NO}_3$, $^{18}\text{O-NO}_3$, $^{13}\text{C-DIC}$, $^{13}\text{C-Ethanol}$, $^{13}\text{C-Biomass}$, and $^{13}\text{C-Calcite}$).
28 Most of the calibrated microbiological parameter values at field scale did not change more
29 than one order of magnitude from those obtained at batch scale, which indicates that
30 parameters determined at the batch scale can be used as initial estimates to reproduce field
31 observations provided that groundwater flow is well known. In contrast, the calcite
32 precipitation rate constant increased significantly (fifty times) with respect to batch scale. The
33 incorporation of isotope fractionation into the model allowed to confirm the overall
34 consistency of the model and to test the practical usefulness of assessing the efficiency of EIB
35 through the Rayleigh equation approach. The large underestimation of the Rayleigh equation
36 of the extent of EIB (from 10 to 50 %) was caused by the high value of hydrodynamic
37 dispersion observed in this fractured aquifer together with the high reaction rates.

40 **1 Introduction**

41 Nitrate is one of the most prevalent and common groundwater contaminants (European
42 Environment Agency, 2007; Organisation for Economic Co-operation and Development, 2008;
43 Rivett et al., 2008). Excessive ingestion of nitrates from polluted drinking water and their
44 subsequent conversion to nitrites can induce methemoglobinemia in humans and potentially
45 play a role in the development of cancers (Fan and Steinberg, 1996; Fewtrell, 2004; Höring and
46 Chapman, 2004). Therefore, the European Union has established maximum concentrations of
47 nitrate and nitrite in drinking water of 50 mg/l for nitrate and 0.5 mg/l for nitrite. The
48 proportions of groundwater bodies at high risk of nitrate pollution (showing mean nitrate
49 concentrations greater than 25 mg/l) were reported as 80% in Spain, 50% in the UK, 36% in
50 Germany, 34% in France and 32% in Italy (European Environment Agency, 2007). The high
51 nitrate concentrations decrease the availability of water for domestic uses. Consequently,
52 many water supply wells have been abandoned (Gierczak et al., 2007). Due to its minimal cost,
53 the most common solution to nitrate pollution has been to mix polluted and clean
54 groundwater. Nevertheless, this solution is extremely limited by water scarcity in
55 Mediterranean and/or (semi-) arid countries, a situation that will become worse due to climate
56 change (IPCC, 2007). Even in countries with no water shortage problems, there is often a lack
57 of clean water to mix and dilute groundwater with high nitrate concentrations (Stuart et al.,
58 2011; Veraart et al., 2014). In this context, it is necessary to implement other solutions to
59 improve the quality of the groundwater.

60 Many technologies are available for treating nitrate in groundwater, such as reverse
61 osmosis, ion exchange, electrodialysis, and chemical and biological denitrification (McAdam
62 and Judd, 2007; Schnobrich et al., 2007; Ricardo et al., 2012). Most of these technologies focus
63 on *ex situ* treatments, which are inherently more expensive than *in situ* treatments due to
64 energy consumption and the interference with surface activities (e.g., building a treatment
65 plant) (Della Rocca et al., 2007). Biological denitrification, which is known as Enhanced *In situ*

66 Biodegradation (EIB), has environmental and economic advantages over other methods
67 because it is simple, selective, and cost effective (Smith et al., 2001). EIB is defined as a process
68 in which organic carbon is injected into the groundwater through injection wells to enhance
69 microbial denitrification. During this process, nitrate is reduced to dinitrogen gas by anaerobic
70 facultative bacteria that use nitrate as the electron acceptor and that are ubiquitous in surface
71 water, soil and groundwater (Beauchamp et al., 1989). This technology is feasible for cleaning
72 nitrate-polluted groundwater and meeting drinking water standards (Matějů et al., 1992; Khan
73 and Spalding, 2004; Vidal-Gavilan et al., 2013).

74 Geochemical interactions occur between the biodegradation reactants and the porous
75 geological medium in response to biodegradation reactions. These interactions may play a
76 critical role in the implementation of EIB in aquifers. Because of the production of dissolved
77 inorganic carbon (DIC) and pH alteration, carbonate mineral dissolution/precipitation is
78 induced by changes in the initial hydrogeological and hydrochemical properties of the aquifer
79 by heterotrophic biodegradation (Rodríguez-Escobedo et al., 2014). Moreover, dinitrogen gas
80 production can lead to a modification of the hydraulic conductivity (Amos and Mayer, 2006).
81 These changes can modify the hydrogeological characteristics of the aquifer and modify the
82 efficiency of the groundwater treatment (Noiriel et al., 2012).

83 Another important factor when monitoring EIB in the field is the dilution caused by
84 hydrodynamic dispersion of nitrate rich water and water with lower nitrate levels (e.g.,
85 recharge). Even without any entrance of clean groundwater, dilution will occur in the fringe of
86 the cleaned groundwater plume from EIB and polluted groundwater. Because of dilution, a
87 decrease in nitrate concentration cannot always be attributed to degradation. Monitoring the
88 changes in the nitrogen and oxygen isotope ratios of nitrate ($\delta^{15}\text{N-NO}_3^-$ and $\delta^{18}\text{O-NO}_3^-$) allows
89 the degradation to be identified (Otero et al., 2009; Puig et al., 2013; Carrey et al., 2014) and
90 therefore nitrate transformation and dilution to be distinguished. In EIB applications, this
91 distinction improves the characterization of the clean groundwater plume and allows nutrient

92 injection to be optimized, reducing treatment costs. As NO_3^- is consumed, the residual NO_3^-
93 becomes enriched in the heavy isotopes ^{15}N and ^{18}O , and the denitrification reaction follows a
94 Rayleigh distillation process (Eq.1):

$$95 \quad R_s = R_{s,0} f^{(\alpha-1)} \quad (1)$$

96 where R_s is the stable isotope ratio (i.e., $^{15}\text{N}/^{14}\text{N}$; $^{18}\text{O}/^{16}\text{O}$) of the fraction of molecules
97 remaining, f ; $R_{s,0}$ is the initial isotopic composition of the molecule; and α is the kinetic isotopic
98 fractionation factor of the transformation process, which is often represented as the kinetic
99 isotopic enrichment factor ϵ (in permil, ‰), where $\epsilon = (\alpha-1)$.

100 Despite that many studies have characterized the isotopic processes associated with
101 biodenitrification by using the Rayleigh equation, some of the most recent works have shown
102 that this equation does not always give accurate results at the field scale (Abe and Hunkeler,
103 2006; van Breukelen, 2007; van Breukelen and Prommer, 2008; Green et al., 2010; van
104 Breukelen and Rolle, 2012). It must be mentioned that all of these studies focused on natural
105 attenuation processes while none on enhanced biodenitrification and fractured aquifers. The
106 differences between Rayleigh-determined and field-scale results are caused because the
107 Rayleigh equation was developed for a closed system (van Breukelen, 2007) and does not
108 account for hydrodynamic dispersion that tends to attenuate isotopic variations. These
109 limitations have been addressed by incorporating isotope fractionation processes into
110 numerical or analytical reactive transport models that account for hydrodynamic dispersion
111 (van Breukelen and Prommer, 2008).

112 In addition to nitrate isotopes, other isotopes such as carbon isotopes are also involved in
113 EIB, and can help to quantify the reaction network (biological reactions and geochemical
114 interactions). The inclusion of dissolved inorganic carbon isotopes ($\delta^{13}\text{C}\text{-DIC}$) into the
115 biogeochemical model, which are involved in both direct (oxidation of organic carbon) and
116 indirect processes (carbonate mineral interaction) of enhanced biodenitrification, is expected

117 to allow better evaluations of the consistency of the model due the central role that $\delta^{13}\text{C-DIC}$
118 plays in the overall reaction network (Rodríguez-Escales et al., 2014).

119 In this context, a field-scale reactive transport model (RTM) of EIB integrating hydrology,
120 microbiology, geochemistry, and isotope fractionation can provide significant benefits for the
121 planning, characterization, monitoring and optimization of this technology in field applications.
122 The integration of all the processes allows the evaluation of their relationships with each other
123 and the prediction of secondary processes such as induced mineral precipitations or
124 dissolution.

125 Several studies have evaluated biodenitrification using numerical models at different
126 scales (Smith et al., 2001; Chen and MacQuarrie, 2004; Lee et al., 2006; André et al., 2011;
127 Mastrocicco et al., 2011; Boisson et al., 2013). However, few studies have focused on
128 modelling enhanced biodenitrification (André et al., 2011; Mastrocicco et al., 2011; Boisson et
129 al., 2013), and only one study has been performed at the field scale (Boisson et al., 2013).
130 Furthermore, few studies have examined the effects of geochemical interactions on
131 biodenitrification within the aquifer matrix (Chen and MacQuarrie 2004) and only a few have
132 explored the potential use of isotope fractionation for monitoring biodenitrification (Lehmann
133 et al., 2003; Chen and MacQuarrie, 2004).

134 The models that have evaluated biodenitrification at the field scale (Chen and
135 MacQuarrie, 2004; Lee et al., 2006; Boisson et al., 2013) do not consider all of the processes
136 involved. The most complete model, which was presented by Chen and MacQuarrie (2004),
137 was applied to a sedimentary aquifer under natural attenuation conditions and did not take
138 into account all of the isotopes modified by biodenitrification (only $^{15}\text{N-NO}_3$). Furthermore, no
139 field integrated model described flow and transport through fractured media, which are
140 characterized by higher heterogeneity with more complex hydrological conditions. Only one
141 model has been developed for this type of geological formation, but it concerns the simulation
142 of push-pull test involving only microbiological processes (Boisson et al., 2013).

143 Because of this lack of knowledge, the aim of this paper is to develop a reactive
144 transport model that considers microbiological processes, geochemical interactions, and
145 complete isotope geochemistry during EIB in a fractured media at the field scale. In fractured
146 aquifers, hydrogeological parameters such as heterogeneity, connectivity between the fracture
147 networks, flow dynamics, and porosity differ notably from those in more extensively tested
148 alluvial aquifers and may pose difficulty for the modeling of *in situ* technologies. The model
149 focuses on microbiological processes, such as exogenous and endogenous nitrate and sulfate
150 respiration coupled with microbial growth and decay, geochemical processes, such as the
151 precipitation of calcite, nitrate isotopic fractionation, including $\delta^{15}\text{N-NO}_3^-$ and $\delta^{18}\text{O-NO}_3^-$, and
152 carbon isotope interactions. In addition, once the model was constructed, the extent of
153 biodenitrification using nitrate isotopes was also evaluated with the Rayleigh equation to
154 assess its use from a practical perspective in EIB applications. To our knowledge, this is the first
155 reactive field-scale model of EIB in the literature which considers microbiological, geochemical,
156 and isotopic processes in one integrated model.

157

158 **2 Materials and Methods**

159 **2.1 Field site description and model code**

160 The model aimed to simulate a slug injection experiment conducted as part of an EIB
161 field experiment described in Vidal-Gavilan et al. (2013). EIB was carried out in an unconfined,
162 carbonated, and well-connected fractured aquifer using ethanol as the organic carbon source.
163 The site was located in the central part of the Osona region (442270, 4647255 UTM31/ETR89;
164 100 km north of Barcelona, Spain). The aquifer, with an extent 1260 km², is recognized as
165 being vulnerable to nitrate pollution due to the large amount of pig farming in the area and
166 the shallow water table. Nitrate levels in the groundwater have reached 200 mg/L or more for
167 the last 10-20 years (Otero et al., 2009), and the natural attenuation rates in the aquifer were
168 not sufficient to guarantee safe water (Otero et al., 2009). The experimental site covers an

169 area of approximately 1000 m² and was monitored with six full screened piezometers with an
170 average depth of 12.5 m.b.s. (432.5 m a.s.l.) (Fig. 1). The screening levels covered the aquifer
171 thickness (4-5 m). Before application of EIB, pumping and bromide-tracer tests were carried
172 out to characterize the hydrogeological parameters and flow conditions. The pumping test
173 indicated good connectivity between the boreholes despite being in a fractured aquifer. It also
174 indicated a relatively homogeneous effective permeability of approximately 5 m/d. To
175 determine the flow velocity and dispersivity, a tracer test was performed with bromide
176 (conservative ion) under natural flow conditions. IP-1 was used as the injection point of the
177 bromide, and MW-2 and MW-3 were used as observation wells. Bromide was monitored at
178 three depths (11 m m.b.s., 12 m.b.s., 13 m.b.s.), which covers the full depth of the
179 piezometers. The results of these field tests indicated that this fractured media could be
180 assumed as an equivalent porous medium with a faster flow in the depth between IP-1 and
181 MW-2 (described in subsection 2.2). An extended description of the field site can be found in
182 section 1 of the supporting information.

183 The EIB was performed for five months and then stopped. Once the background
184 concentration of nitrate had recovered (120 mg NO₃⁻/L, 1.9 mM), a slug injection of ethanol
185 was performed. The presented model was focused on this slug injection and its subsequent
186 monitoring during two days. During the slug injection a total volume of ethanol solution of 1
187 m³ was injected. The concentration was 630 mg/l of ethanol and it was assumed that its
188 entrance to the aquifer was similar throughout the screened interval of the injection well. The
189 injected solution was prepared at the surface using groundwater from an upstream well with
190 the same hydrochemical composition. All denitrification experiments were developed under
191 natural flow conditions. An extended description of the experiment is detailed in the
192 supporting information.

193 The model code used was PHAST (Parkhurst et al., 2010). This code was used both for
194 conservative and reactive transport simulations. PHAST couples the flow simulator HST3D and
195 the geochemical model PHREEQC-2 (Parkhurst and Appelo, 1999).

196 **2.2 Conservative transport**

197 The conservative transport model was constructed based on the bromide tracer test.
198 Because the field tests demonstrated that this fracture medium could be assumed to be an
199 equivalent porous medium, we used the transport equations for porous media. PHAST solved
200 the conservative transport model following equation 2:

$$201 \quad \phi \frac{\partial c_i}{\partial t} = -q \nabla c_i + \phi \nabla (D \nabla c_i) \quad (2)$$

202 where D is the dispersion tensor [L^2T^{-1}], q is the Darcy's velocity ($[LT^{-1}]$ which is related to
203 hydraulic conductivity [LT^{-1}] and groundwater gradient [-]), ϕ is the porosity [-]. The model was
204 solved under transient conditions. The geometry of the model involved a cross section (2D)
205 between the injection point (IP) and monitoring well 3 (MW-3) (located 26.5 m from the IP)
206 along the groundwater flow direction and considered a saturated thickness of 4 m (Fig. 1). The
207 aquifer was treated as unconfined with constant heads and concentrations on the up-gradient
208 and down-gradient boundaries (8.51, 8.57 m.b.s.). Constant head values were assigned to
209 simulate the hydraulic gradient observed during the field experiments (2.3×10^{-3}). Because
210 there was not any other flow except the slug injection (e.g. rainfall, external pumping), zero
211 flow conditions were assigned to the upper and bottom boundaries.

212 Simulations were carried out with a hydraulic conductivity of 7.5 m/d and an effective
213 porosity of 7×10^{-4} , both values are in the range of parameters obtained in the field. The faster
214 flow at depth between the injection point (IP) and MW-2 was characterized by a higher
215 hydraulic conductivity (32 m/d)). The average groundwater flow velocity was approximately 30
216 m/d. The model was calibrated using two dispersivity coefficients depending on the distance
217 to the injection point (1.4 m from 0 to 12.5 m in the domain and 6.5 m from 12.5 to 26.5 m (in

218 X axis)). Then following the Peclet and Courant numbers (Eq. 2 and 3, respectively), we used a
219 uniform 0.5 x 0.1 m grid and a time step of 0.005 days (total time was 3.5 d).

$$220 \quad C = \frac{\Delta l}{\alpha} < 2 \quad (3)$$

$$221 \quad Pe = \frac{v\Delta t}{\Delta l} < 1 \quad (4)$$

222 where Δl is the size of the cell (length and height) [L], α is the dispersivity coefficient
223 (longitudinal or vertical) [L], v is the groundwater velocity [LT^{-1}], and Δt is the time step [T].

224 **2.3 Biogeochemical reactive transport model**

225 When the conservative model was finished, reactive processes were added to the same
226 PHAST model. Since PHAST uses the original PHREEQC-2 database syntax, arbitrary equilibrium
227 and non-equilibrium reaction networks were defined as in Rodríguez-Escales et al. (2014)
228 which simulated EIB at batch scale with PHREEQC. Kinetic reactions such as ethanol
229 degradation, bacterial growth and decay, calcite precipitation, and all the isotopic reactions
230 not being part of the standard database, were incorporated into the module in the form of
231 simple BASIC routines, following the equations described in Table 1 (Equations 5-8). For
232 equilibrium reactions, the reaction constants were used directly as provided by the PHREEQC-2
233 standard database. The model was run in transient conditions considering the initial heads
234 measured before the biodenitrification started.

235 **2.3.1 Microbiological processes**

236 Both nitrate and sulfate respiration coupled to microbial growth were modeled using
237 double Monod kinetics (Table 1). The stoichiometric relationships were based on Reactions 1
238 and 2, which summarize the redox respiration reaction in nitrate and sulfate reduction coupled
239 with microbial growth. In those reactions, the biomass was considered to have an average
240 chemical composition of $C_5H_7O_2N$ (Porges et al., 1956). The portions of the substrate's
241 electrons used for cell synthesis during these anoxic processes were assumed to be 0.682 and

242 0.882 moles C-biomass/moles C-ethanol for denitrification and sulfate-reduction, respectively,
 243 based on the calculations described in (McCarty, 1975).

245 Reaction 1

247 Reaction 2

248 The model incorporated two types of biomass: the denitrifier and the sulfate reducing
 249 biomass. Both types of biomass were assumed to remain attached to the sediment. Because
 250 the model was focused on a system with a mature biofilm, the initial value of the denitrifier
 251 biomass used in the model was taken as the maximum value of the biomass simulated in a
 252 previous batch model using the same composition groundwater of the field site (Supporting
 253 Information). The initial value was 8×10^{-4} M, and we applied the same initial concentration for
 254 both types of biomass. This approach was also followed by Tang et al. (2013), who used the
 255 same initial value for different populations (denitrifiers, Fe reducers, sulfate reducers,
 256 fermenters and methanogens) in a model of uranium redox transformation.

257 **2.3.2 Geochemical processes**

258 The main abiotic geochemical process considered was calcite precipitation since
 259 Rodríguez-Escales et al. (2014) observed that when ethanol was used as the organic carbon
 260 source, calcite precipitation was induced. The precipitation rate was modeled using
 261 expressions 8-9 from Table 1. Potential changes in porosity due to calcite precipitation were
 262 calculated using the Equation 10.

263
$$\Delta\phi(\%) = \left(\frac{V_o - \left(\frac{M_{cc}}{\rho_{cc}} \right)}{V_t} \right) \times 100 \quad (10)$$

264 where ϕ is the porosity [-], V_o is the initial void volume [L^3], ρ_{cc} is the calcite density [M L^{-3}], M_{cc}
 265 is mass of precipitated calcite [M], and V_t is total volume [L^3].

266 Degassing of N₂, which is the most important gas in denitrification processes, was
267 evaluated calculating its partial pressure and comparing it with total hydrostatic pressure
268 which was 1 atm at the water table and 0.1 higher per 1 m depth below the water table (it was
269 an unconfined aquifer). When the total pressure (the sum of partial pressures of the various
270 gases) was higher than hydrostatic pressure, it was considered that degassing could occur in
271 the aquifer.

272 **2.3.3 Stable isotope geochemistry model**

273 The isotopic fractionation of nitrogen and oxygen in nitrate and of carbon in C-
274 containing compounds was included in the model. Assuming Monod degradation kinetics, the
275 rates of the heavy (¹⁵N-NO₃⁻, ¹⁸O-NO₃⁻, ¹³C-ethanol) and light (¹⁴N-NO₃⁻, ¹⁶O-NO₃⁻, ¹²C-ethanol)
276 isotopes from the batch experiment were modeled as described in (van Breukelen and
277 Prommer, 2008) (Equations 10-11 from Table 1). The nitrate enrichment factor was based on
278 Vidal-Gavilan et al. (2013) (-12.9 ‰ and -8.8 ‰ for the nitrogen and oxygen of nitrate,
279 respectively). The carbon isotope fractionation of ethanol during denitrification was taken
280 from Rodríguez-Escales et al. (2014) (ε = +8 ‰). Because these enrichment factors were
281 determined under laboratory conditions (closed system), they were only affected by
282 degradation processes, and they could be used at the field scale (Torrentó et al., 2011; Carrey
283 et al., 2013). Furthermore, laboratory conditions were very similar to field conditions: the
284 groundwater and sediments used were taken from the site and the *in-situ* groundwater
285 temperature (15°C) was maintained. Nevertheless, to our knowledge, the enrichment factor
286 for ethanol during sulfate reduction has not yet been reported in the literature. The most
287 similar conditions were found in Govert and Conrad (2008). They determined the enrichment
288 factors for the oxidation of acetate by heterotrophic sulfate-reducers (range between ε = +1.8
289 ‰ and -19.1 ‰). We used these values because acetate is a metabolite of ethanol in many
290 sulfate reduction metabolisms (Nagpal et al., 2000). The large difference between the two
291 fractionation factors from the different metabolic pathways that the sulfate reducers used to

292 reduce the acetate (Goevert and Conrad, 2008). Note that enrichment factors might be
293 dependent on temperature (Elsner, 2010). Therefore, we determined the enrichment factor
294 for ethanol oxidation during denitrification at the *in-situ* groundwater temperature of 15°C.
295 With respect to the ethanol oxidation coupled to sulfate-reduction, the enrichment factors
296 were only available at 30 and 37°C. Therefore, we applied the lower and higher end of the
297 range ($\epsilon=+1.8$ ‰ and -19.1 ‰) and expect that any influence of temperature is captured by
298 this wide range.

299 The carbon isotope network was based on Rodríguez-Escales et al. (2014), who extended
300 the model of van Breukelen et al. (2004), which is summarized in Figure 2 and Table 2. Note
301 that in this model the isotopic effect in the organic carbon (ethanol) was simplified to one
302 value that was representative of overall metabolism. Compared to the batch models of
303 Rodríguez-Escales et al. (2014), we also included the oxidation of ethanol due to sulfate
304 reduction and the decay of sulfate-reducing biomass. To simplify the model and because CO₂
305 degassing was not quantitatively important (results not shown), we considered that the
306 contribution of degassing to ¹³C-DIC was negligible and then it was not included in the
307 numerical model. The model was calibrated with the $\delta^{13}\text{C}$ -DIC observations.

308 The $\delta^{13}\text{C}$ contents of heterotrophic biomass (e.g. *Pseudomonas aeruginosa*) have been
309 found to vary from -10.3 to -25.4 ‰ (Blair et al., 1985; Coffin et al., 1990). We adopted -20 ‰
310 for both the denitrifiers and sulfate-reducers. For calcite precipitation, the $\delta^{13}\text{C}$ -DIC
311 modification was calculated following the procedure of van Breukelen et al. (2004). They
312 calculated the $\delta^{13}\text{C}$ -CaCO₃ precipitation by applying the equilibrium fractionation factors to the
313 different inorganic carbon species and calcite (as defined by Mook (2000)). At 15°C, $^{13}\epsilon_{a/b}$ was -
314 10.12 ‰, $^{13}\epsilon_{c/b}$ was -0.49 , and $^{13}\epsilon_{s/b}$ was $+0.41$, where *a* is the dissolved CO₂, *b* is the dissolved
315 HCO₃⁻, *c* is the dissolved CO₃⁻², and *s* is the solid calcite. Considering these fractionation factors
316 and the initial $\delta^{13}\text{C}$ -DIC value, we calculated an initial $\delta^{13}\text{C}$ -CaCO₃ value of -11.3 ‰. This value
317 was in the range described by Mook (2000).

318 **2.3.4 Evaluation of the extent of Enhanced *in situ* Biodegradation: RTM versus Rayleigh**
319 **equation**

320 In order to evaluate the use of the Rayleigh equation to determine the extent of
321 biodegradation from a practical perspective in field-scale EIB applications, we compared
322 results from the RTM with those from the Rayleigh equation. In general, the extent of
323 biodegradation (B%) is related to the fraction of degradation of the target pollutant, in this
324 case nitrate (Eq. 16).

$$325 \quad B (\%) = (1 - f_{\text{deg}}) \times 100 \quad (16)$$

326 where f_{deg} is the remaining fraction of the target compound compared with initial
327 concentration as a consequence of degradation.

328 For the case where the extent of biodegradation is calculated using the Rayleigh
329 equation, B_{Rayleigh} (%), the degradation fraction ($f_{\text{deg, Rayleigh}}$) was related to the simulated isotope
330 signals (Eq. 17) (van Breukelen, 2007).

$$331 \quad f_{\text{deg, Rayleigh}} = e^{\Delta/\epsilon} \quad (17)$$

332 where Δ (%) represents the isotopic shift of a sample with respect to the source ($= \delta_s - \delta_{s,0}$),
333 and ϵ represents the kinetic isotopic enrichment factor, ϵ (‰). The extent of biodegradation
334 calculated using the RTM, B_{RTM} (%), was calculated by comparing the nitrate concentration
335 with the initial one in time (Eq. 18), and B_{RTM} (%) was calculated using equation 16.

$$336 \quad f_{\text{deg, RTM}} = \frac{[\text{NO}_3^-]}{[\text{NO}_3^-]_0} \quad (18)$$

337 where $[\text{NO}_3^-]$ is nitrate concentration [ML^{-3}] and $[\text{NO}_3^-]_0$ is the initial concentration of nitrate in
338 aquifer ($1.9 \times 10^{-3} \text{ ML}^{-3}$).

339 The difference between the extents of EIB calculated by the Rayleigh equation and the
340 RTM is evaluated by the theta value, Θ (Eq. 19). This approach was used in several studies to
341 calculate the underestimation of the (assumed) first order rate constant, since $-\ln(f)$, where
342 f is the fractionation of contaminant remaining due to biodegradation (Abe and Hunkeler,
343 2006; van Breukelen and Prommer, 2008).

344
$$\theta = \left(1 - \frac{k_{\text{Rayleigh}}}{k_M}\right) \times 100 = \left(1 - \frac{\ln f_{\text{deg,Rayleigh}}}{\ln f_{\text{deg,RTM}}}\right) \times 100 \quad (19)$$

345 When θ equals 0% the Rayleigh equation predicts an equal extent of EIB as calculated in the
 346 model. However, θ usually $> 0\%$ and the Rayleigh equation underestimates the extent of
 347 degradation. For example, if θ is 50% or 90%, the Rayleigh equation underestimates the actual
 348 extent of EIB (expressed at the pseudo first-order rate constant) with a factor 2 or 10,
 349 respectively. Theta values are discussed considering the Peclet number (Pe) (Eq. 4) and the
 350 Damkhöler number (Da) (Eq. 20),

351
$$Da = \frac{T_{\text{adv}}}{T_{\text{reac}}} \quad (20)$$

352 where T_{adv} is referred to advective time (distance divided by average velocity) and T_{reac} to
 353 characteristic time of reaction. This last one is defined similarly by Henze (2008) in Equation
 354 21 and is valid when $K_{S,ED}$ is higher than the initial ED concentration.

355
$$T_{\text{reac}} = \frac{1}{k_{\text{max}}} \frac{K_{S,ED} + [ED]_0}{[X]_0} \frac{[EA]_0}{K_{S,EA} + [EA]_0} \quad (21)$$

356 where $[ED]_0$, $[EA]_0$, and $[X]_0$ are to initial conditions of the system, defined in Table 3.

357 **2.4 Initial conditions and calibration process**

358 The initial hydrochemistry and the temperature of the groundwater as well as of the injection
 359 groundwater are shown in Table 3. These concentrations were used as initial and boundary
 360 concentrations in the model. The sediment of the aquifer was composed of calcite (27.2 wt.%),
 361 muscovite ($KAl_2(AlSi_3O_{10})(OH)_2$, 26.2 wt.%), and quartz (23.1 wt.%), with small amounts of
 362 albite ($NaAlSi_3O_8$, 10.3 wt.%), dolomite (7.7 wt.%), sudoite ($Mg_2(Al; Fe^{3+})_3Si_3AlO_{10}(OH)_8$,
 363 4.9 wt.%), and pyrite (0.6 wt.%) (Torrentó et al., 2011). In the model, we only considered
 364 calcite due to its intrinsic interaction with denitrification because of inorganic carbon
 365 production. Moreover, it was the major mineral in the sediment. All the calibrated model

366 parameters from both the conservative transport model (hydraulic conductivity, porosity,
367 dispersivity) and the reactive transport model (maximum consumption rate, saturation
368 constants, decay and precipitation rates) were manually calibrated. The initial values for the
369 conservative model parameters were based on the values observed in the field tests and the
370 model was calibrated taking into account the experimental bromide observations monitored at
371 three different depths in piezometers MW-2 and MW-3 (Fig. 1). In the reactive model, the
372 initial ones were based on a model of batch experiments using material from this site
373 (Rodríguez-Escales et al. 2014). For the sulfate reduction process the initial parameters were
374 taken from Nagpal et al. (2000), who modeled sulfate reduction by using ethanol as an organic
375 carbon source in a batch system. The model was calibrated by fitting the measured
376 concentrations (ethanol, nitrate, sulfate, calcium, dissolved inorganic carbon, pH, and isotope
377 geochemistry ($\delta^{15}\text{N-NO}_3^-$; $\delta^{18}\text{O-NO}_3^-$; $\delta^{13}\text{C-DIC}$)) and the saturation index of calcite in MW-2
378 and MW-3.

379

380 **3 Results and discussion**

381 **3.1 Conservative transport model**

382 The results of the conservative transport model are shown in Figure 3. Multilevel
383 sampling indicated an earlier arrival of bromide in the deeper part of MW-2 (Fig. 3), whereas
384 most of the bromide mass was detected at 0.14 d, a peak was observed at 0.05 d. Moreover,
385 the concentration in the deeper part (reaching 20 mM) was twice those at shallower depths
386 (approximately 10 mM). These differences in bromide concentration at different depths were
387 not observed in MW-3, which indicates a homogenization of bromide transport along the flow
388 line. Porosity was only related to the secondary porosity because groundwater flow occurs
389 mainly through fractures (Vidal-Gavilan et al., 2013). The obtained dispersivity values (1.4 m
390 (from 0 to 14 m of the domain) and 6.5 m (from 14 to 26 m)) were consistent with the scale

391 (26 m) of the biodenitrification application (Gelhar et al., 1992). Note the small increase of
392 bromide in MW-3 after day two (Fig. 3). We ascribe this increase to a slower groundwater flow
393 component as part of the fracture network with lower hydraulic conductivity or due to the
394 effects of the injection. Nevertheless, because the biodenitrification model extended for only
395 two days, this flow component was considered not quantitatively important and was not
396 included in the model.

397 **3.2 Biogeochemical Reactive Transport Model**

398 **3.2.1 Microbiological processes**

399 The RTM was performed taking the hydrogeological parameters determined in the
400 conservative transport model with refreshed head constants (8.54 and 8.42 m). In this case,
401 the head levels differed from the tracer test and the hydraulic gradient was higher;
402 consequently, the flow velocity increased. The flow velocity during the slug injection in most of
403 the domain was approximately 50 m/d.

404 Figure 4A shows the results of the 2D RTM for the upper and lower ends of wells MW-2
405 and MW-3 using the parameters from Table 4, all of them in the range of published data (Table
406 5). In general, the model fits well the general trend observed in the field and the modeled
407 values matched the observations. Both MW-2 and MW-3 showed decreasing nitrate
408 concentrations until non-detectable levels were present in less than 0.2 days. This rapid
409 reduction in concentration can be attributed to the high activity of biomass that had been
410 stimulated by ethanol during the previous five months. Both the exhaustion of ethanol and the
411 fast groundwater flow increased nitrate concentrations until they reached background levels in
412 MW-2. The modeled nitrate concentration at MW-3 began to increase after less than one day,
413 while the observed concentrations stayed at zero. The later breakthrough of nitrate observed
414 in the field was attributed to the slower flow component described for the tracer test results
415 that was not taken into account in the model (Fig. 3).

416 Undesired sulfate reduction was observed during the slug test, albeit the concentration of
417 injected ethanol was chosen such that only nitrate should deplete. The observed sulfate
418 decreased over time with 0.36 mM in MW-3 (Fig. 4c and 4c'), and H₂S was detected in MW-2
419 and MW-3 odor detection. Note that the ethanol peak matched in time with the decrease of
420 sulfate (Fig. 4). Thus, this anaerobic activity was mainly attributed to an applied excess of
421 ethanol in the subsurface.

422 During the upscaling process (in calibration process), the parameters were adjusted by
423 considering the difference between the bioavailability of nutrients at the batch and field scales
424 (based on the half-saturation constants) and the adaptation of microbial metabolism to the
425 environment (based on decay constants) (Jin et al., 2012). Table 4 shows that the differences in
426 the half-saturation parameters between the batch and field experiments are always less than
427 one order of magnitude, except for the half-saturation of nitrate during denitrification. The
428 decay constant in the field was higher than that from the laboratory (Table 4) because the
429 biomass used in the batch experiments was younger (seven days) than that used at the field
430 scale (five months). Considering the high variability of these parameters (Table 5), we believe
431 that the differences observed between the parameters at the batch and field scales are small
432 enough to set up the batch scale parameters as a good initial approximation to start up in the
433 field scale models.

434 In contrast, the specific growth yields (Y_h) and the maximum rate constant (k_{max}) can be
435 directly transferred from the laboratory to the field scale (Jin et al., 2012). Both parameters are
436 related to the properties of enzymes and pathways of metabolic reactions that are the same in
437 the laboratory and in the field (Table 4). Thus, these values can be directly extrapolated from
438 the laboratory scale to the field scale.

439 **3.2.2 Geochemical processes**

440 Calcite precipitation was confirmed by the decrease of calcium in solution and the
441 increase of the saturation index of calcite (Fig. 4g and 4g'). At this point, an increase in the

442 inorganic carbon in both MW-2 (from 9.5 to 10.8 mM) and MW-3 (from 9.5 to 11.4 mM) was
443 observed due to ethanol oxidation. The saturation index of calcite began at negative values but
444 became positive when inorganic carbon was added to the system due to ethanol oxidation.
445 The precipitation rate constant differed between batch scale (1×10^{-10} M/s) and field scale ($5 \times$
446 10^{-9} M/s) (Table 4). The value in the field was unexpectedly fifty times higher than that from
447 the laboratory experiments. This difference may have been caused by the sediment being
448 deposited in the reactor in the batch experiment, which limited the growth of calcite from the
449 standing solution to the crystals in the sediment. In the field the contact between groundwater
450 and the solid matrix was higher due to the transport of groundwater through the
451 microfractures. The field precipitation rate constant is consistent with the large range of values
452 from the literature (1.0×10^{-7} , 1.2×10^{-7} , and 2.3×10^{-10} M/s from Inskeep and Bloom (1985),
453 Busenberg and Plummer (1982) and van Breukelen et al. (2004), respectively).

454 The modeled values of pH slightly increased from 6.8 before injection to 7.1 (MW2) and 7
455 (MW3) following the injection (Fig. 4). The timing of this increase matched that of the increase
456 of the calcite saturation index in both piezometers. After 0.5-1 days, it recovered to the
457 previous value of 6.8. The overlapping in the error of the measured pH values does not allow
458 evaluating the basification of the media as shown by the modeled values (Fig. 4). The observed
459 field values may indicate that the system was buffered by the presence of carbonate minerals
460 which masked the effect of produced inorganic carbon from the EIB.

461 Regarding the degassing of dinitrogen gas, the results indicated that the sum of the
462 partial pressures were higher than hydrostatic pressure when denitrification occurred
463 indicating that degassing of the system could be induced (Fig. 5). Also, the degree of
464 overpressure due to denitrification was less than 1 bar. Considering the short time frame of
465 overpressure conditions in the studied aquifer section (≈ 1 day) we assumed for model
466 simplicity that the degree of actual degassing was limited and most of the produced N_2 gas
467 remained in dissolved state while flowing out of the aquifer section. The potential formation of

468 bubbles and how they change the hydraulic conductivity of the aquifer was thus not evaluated.
469 Although we believe that formed gas was not trapped in this media because of the well
470 connection between the horizontal and vertical fractures network, further research is needed.

471 Biofilm growth, microbial-induced mineral precipitation or dissolution and bubble
472 formation can modify the hydrologic properties of the media (e.g., hydraulic conductivity,
473 dispersivity and porosity) (Soares et al., 1991; Thullner, 2010). In our model, we assumed that
474 the hydrologic properties of the media were constant due to the short duration of the field
475 test (two days). In our case, the amount of biomass did not change significantly and remained
476 at the same order of magnitude (Fig. 4) assuming bioclogging was negligible. The maximum
477 relative change of porosity due to calcite precipitation at the end of the model (2 days) was
478 less than 0.002% across the entire model domain. This change was calculated using Eq. 9.
479 Then, calcite precipitation did not significantly modify the hydraulic properties either.

480 **3.3 Stable isotope geochemistry model**

481 The modeled N and O isotope ratios matched the observation data reasonably well in
482 MW-2 (Fig. 6). The simulated delta values are only shown for nitrate concentrations that
483 exceed 1 mg/ because analytical methods used in Vidal-Gavilan et al. (2013) for nitrate
484 isotopes need a minimal concentration of nitrate similar to that concentration. In MW-2, the
485 $\delta^{15}\text{N-NO}_3^-$ and $\delta^{18}\text{O-NO}_3^-$ values increased from 13.5 ‰ to 24.4 ‰ and from 5.8 to 12 between
486 days 0.1 and 0.3 at the same time as nitrate decreased (Fig. 4a and 4a'). On the other hand,
487 when the nitrate concentrations increased to the background values of the aquifer, the
488 isotopic values also decreased to their initial values.

489 Variations of $\delta^{13}\text{C-DIC}$ are controlled by the sources of carbon that are oxidized, including
490 physical (e.g., CO_2 degassing, carbonate precipitation or dissolution) and biochemical
491 processes (e.g., microbial respiration). Thus, all of the processes that affect the $\delta^{13}\text{C-DIC}$ signal
492 were included in the model, including the two types of respiration (exogenous and
493 endogenous) for both nitrate and sulfate reduction and calcite precipitation. Although the

494 modeled values of $\delta^{13}\text{C}$ -DIC do not follow the general trend of the experimental field values,
495 they indicate the main processes that affect their variation (Fig. 7). Despite the important
496 fractionation due to the oxidation of ethanol and independent of the fractionation factor of
497 ethanol used in sulfate reduction, the $\delta^{13}\text{C}$ -DIC values did not change considerably (maximum
498 variation of 2 ‰) (Fig. 7, which only shows results of $\epsilon_{\text{eth/sulf}}=+1.8$ ‰ because no difference
499 were between those and results using $\epsilon_{\text{eth/sulf}}=-19.1$ ‰). The differences between the field and
500 modeled $\delta^{13}\text{C}$ -DIC changes were attributed to the natural variations of this isotope in
501 groundwater (the $\delta^{13}\text{C}$ -DIC values in the municipal well, which represent the natural
502 background, oscillated from -11 ‰ to -8 ‰ during the slug injection test). So, despite EIB
503 produces a change in the $\delta^{13}\text{C}$ values, natural variation in this site is much more important and,
504 consequently, the $\delta^{13}\text{C}$ variation becomes masked.

505 **3.4 Evaluation of the extent of Enhanced *in situ* Biotenitrification: RTM** 506 ***versus* Rayleigh equation**

507 In this case study, the Rayleigh equation underestimates the extent of enhanced *in situ*
508 biotenitrification compared with the RTM simulations as it is observed in previous studies of
509 natural attenuation (Abe and Hunkeler, 2006; van Breukelen and Prommer, 2008; Green et al.,
510 2010; Lutz et al., 2013) (Fig. 8). The underestimation of the Rayleigh equation is associated
511 with its intrinsic limitation when used at the field scale (van Breukelen et al. 2007), where
512 other processes such as mixing, sorption or dispersion occur, compared to laboratory
513 experiments. In our case, we attributed the underestimation (from ten times to twice) to the
514 fractionation that occurs at the boundary between the groundwater cleaned by EIB and
515 polluted groundwater where mixing and dispersion processes are more important than in the
516 center of the plume (Fig. 8). Nevertheless, the spatial and temporal variations in the extent of
517 biotenitrification were qualitatively similar among RTM and Rayleigh equation results. This

518 indicates that from a practical point of view, the Rayleigh equation can be applied to obtain an
519 initial conservative estimate of the extent of EIB.

520 Figure 8 also shows that the extent of biodenitrification in different parts of the
521 denitrified groundwater plume and in time is underestimated by the Rayleigh equation to
522 different degrees (from 10-50 %). The T_{reac} and the T_{adv} are respectively 0.15 and 0.53 d, which
523 conform to a Da number of 3.6. The determined T_{reac} is very consistent with Figure 4, where
524 complete degradation was achieved in 0.2 d. On the other hand, the Peclet number was 200,
525 indicating that at this site the flow was highly advective. Considering these two values and Abe
526 and Hunkeler's (2006) work, the underestimation should be around 10%, which agrees with
527 the first stages of our case (until 0.8 d) where underestimation was between 10 and 30% (Fig.
528 8). Until this time the active plume of denitrification (with complete denitrification, see
529 percentage of degradation in Figure 8) still resided in the model domain. Nevertheless, when
530 the bulk of the denitrified plume moved outside of the model domain, underestimation
531 increased until 50%. This rise was associated with the relative importance of dispersion and
532 mixing processes in the upstream fringes of the plume. The degree of underestimation was
533 greater than those in other studies (Abe and Hunkeler, 2006; van Breukelen and Prommer,
534 2008; Lutz et al., 2013), most likely because of the considerably higher dispersivity coefficients
535 observed at our study site (around one order of magnitude higher than those studies
536 considering the scale of transport). Nonetheless, our results were in coherence with Green et
537 al. (2010) who determined that the apparent denitrification rate constant was 10 times lower
538 than the actual rate constant in case of highly heterogeneous aquifer conditions that induce
539 strong mixing processes.

540 In summary, the use of the Rayleigh equation in EIB applications will give a conservative
541 estimate of the degree of denitrification, but it will provide a stronger underestimate when
542 mixing processes are more important than reactions (e.g., in highly heterogeneous aquifers).

543 **4 Conclusions**

544 We developed a 2-D reactive transport model of EIB applied in a fractured aquifer that
545 integrates biogeochemical processes as well as isotope fractionation to enable better planning,
546 characterization, monitoring, and optimization of EIB. The reactive transport model was based
547 on the upscaling of previous batch models that used groundwater and core material from the
548 same experimental site. The microbiological processes were up-scaled based on adjustments
549 of the half-saturation and decay constants. Most of the modified microbiological parameters
550 did not differ by more than one order of magnitude, indicating that the initial batch values
551 were a good approximation for the initial field scale modeling. In contrast, the calcite
552 precipitation constant was 50 times larger than in the batch experiments. We attribute this
553 difference to the different conditions between the laboratory and the field; whereas in
554 laboratory, the sediment was deposited in the stagnant reactor hence limiting the growth of
555 calcite, in field there was enhanced contact between groundwater and the solid matrix
556 through the microfractures.

557 Although we assumed the hydraulic properties of the media to be constant over time,
558 we quantified a relative decrease in porosity of less than 0.002% due to calcite precipitation.
559 As the model was focused on the stationary phase of biofilm growth, porosity modification did
560 not change considerably, and degassing was considered negligible. It is important to note that
561 this decrease in porosity due to calcite precipitation was produced exclusively as a result of a
562 slug injection of an organic carbon source. More research is needed to evaluate the relevance
563 of bubble formation due to dinitrogen gas formation and how it can modify the hydraulic
564 properties.

565 The integration of the isotope fractionation into the model allowed us to evaluate the
566 overall model consistency. Compared to the batch scale, where denitrification produced
567 significant changes on $\delta^{13}\text{C-DIC}$, in this field work, $\delta^{13}\text{C-DIC}$ was mainly affected by the natural
568 background variations, and changes due to enhanced bioremediation were not observed.

569 The degree of underestimation of the Rayleigh equation was low (less than 20%) and in
570 agreement with Abe and Hunkeler (2006) when denitrification was going on. On the other
571 hand, when most of the plume passed and denitrification rates became lower, the high
572 dispersivity pushed the degree of underestimation to 50% in the upstream plume fringe.
573 Despite this underestimation, the extents of biodenitrification were qualitatively similar in
574 both the RTM and Rayleigh approaches. This indicates that from a practical point of view and
575 considering its conservative behavior, the Rayleigh equation can be applied to EIB as an easy
576 initial step to evaluate the extent of EIB.

577 Overall, the development of this integrated model allowed improving the knowledge of
578 all the processes occurring during EIB at the field scale in a complex hydrogeological media.
579 Although more research is needed to evaluate the behavior of EIB during long-term
580 experiments, our model can be implemented in other field studies in order to evaluate the
581 concentrations trends, to quantify the importance of secondary processes such calcite
582 precipitation, or to evaluate if Rayleigh equation can be used to quantify the extent of
583 denitrification in field applications.

740 **Figure captions**

741 **Figure 1.** Pilot test layout and cross section considered in the model (modified from Vidal-
742 Gavilan (2013)). IP means Injection Point, and MW means Monitoring Well. The black lines in
743 the cross section near MW-2 and MW-3 indicate the sampling depth.

744 **Figure 2.** Carbon isotope reaction network with different isotope fractionations and initial
745 conditions.

746 **Figure 3.** Modeling of the bromide tracer test. Observations (data points: Δ , 434 m a.s.l.; \bullet ,
747 435 m a.s.l.; \square , 436 m a.s.l.) versus modeling results (lines) (dotted line, 434m.a.s.l.; --435 m
748 a.s.l.; — 436m.a.s.l.).

749 **Figure 4.** Modeling results (lines) versus observations (\bullet) for MW-2 and MW-3. Solid lines
750 correspond to 434 m a.s.l., dashed lines correspond to 435 m a.s.l. Red lines correspond to
751 sulfate-reducer biomass, and green lines represent the results of the conservative model
752 without reactions.

753 **Figure 5.** Modeling results of partial pressure of dinitrogen gas (atm), dotted lines represent
754 the hydrostatic pressure. When the sum of partial pressures, which are mainly governed by
755 dinitrogen gas pressure (results not shown), are higher than hydrostatic pressure degassing
756 exists.

757 **Figure 6.** Simulation of nitrate isotope data. Modeling results (lines) versus observations in
758 MW-2. The results of nitrate isotopes are only shown for nitrate concentrations up to 0.2 mM,
759 where nitrate isotopes analytics were trustworthy. Solid lines correspond to 434 m a.s.l.,
760 dashed lines correspond to 435 m a.s.l. and green lines represent the results of the
761 conservative model without reactions.

762 **Figure 7.** Modelling results (lines) versus observations of $\delta^{13}\text{C-DIC}$ at MW-2 (A) and MW-3 (B).
763 Solid lines correspond to 434 m a.s.l., dashed lines correspond to 435 m a.s.l. The plots
764 correspond to different fractionation factors of ethanol due to sulfate reduction; A
765 corresponds to MW-2 and B to MW-3.

766 **Figure 8.** Temporal-spatial variations of the extents of EIB (%) calculated using the Rayleigh
767 equation and the RTM, the underestimation of the extent of EIB following the Rayleigh
768 equation (theta (%)), and nitrate rate (mM/d).

Table 1. Reactive processes involved in biogeochemical modeling.

Reactive processes		Equation
Biological processes (for nitrate and sulfate reduction)	Exogenous respiration rate	$r_{ED} = -k_{max} \frac{[ED]}{[ED] + K_{S,ED}} \frac{[EA]}{[EA] + K_{S,EA}} [X] \quad (5)$
		$r_{EA} = Qr_{ED} - Sb[X] \quad (6)$
	Biomass rate	$r_X = -Y_h r_{ED} - b[X] \quad (7)$
Geochemical interaction	Calcite precipitation	$r_{min,prep} = K_{obs} (\Omega - 1) \quad (8)$
		$\Omega = \frac{IAP}{K} \quad (9)$
Stable isotope geochemistry model (general rates)	Light isotopes	$r_{z,l} = r_z \frac{[Z_l]}{[Z_l] + [Z_h]} \quad (10)$
	Heavy isotopes	$r_{z,h} = r_z \frac{[Z_h]}{[Z_l] + [Z_h]} (\epsilon + 1) \quad (11)$
ED [ML ⁻³] electron donor concentration EA [ML ⁻³] electron acceptor concentration X [ML ⁻³] biomass concentration k _{max} [T ⁻¹] is the maximum consumption rate of the electron donor (calibrated parameter) K _{S,ED} [M L ⁻³] and K _{S,EA} [M L ⁻³] are the half-saturation constants (calibrated parameter) Q [-] and Y _h [-] are stoichiometric parameters (determined in Reactions 1 and 2) S [-] is stoichiometric parameter for endogenous respiration (0.92, internally calculated by Phreeqc)		b [T ⁻¹] is the decay constant (calibrated parameter) K _{obs} [ML ⁻³ T ⁻¹] is the precipitation rate constant Ω [-] is the saturation state of calcite (calculated) IAP is the ion activity product K is the thermodynamic equilibrium constant at 15°C (from Phreeqc database) ε (‰) is the isotopic enrichment factor (from Vidal-Gavilan et al. 2013; Rodríguez-Escales et al. 2014 and Govert and Conrad (2008)).

Table 2. Equations and enrichment factors considered in carbon isotope network

Process	^{13}C Rate	Kinetic isotope enrichment factor (ϵ)
Oxidation of electron donor: Ethanol \rightarrow DIC	$r_{^{13}\text{C-BM}} = Y_n r_{\text{ED}} \frac{[\text{ED}_n]}{[\text{ED}_i] + [\text{ED}_n]} (\epsilon_{\text{ED/BM}} + 1)$	<u>Denitrification</u> +8 ‰ (Rodríguez-Escales et al., 2014) <u>Sulfate Reduction</u> +1.8/-19.1‰ (Goevert and Conrad, 2008)
Biomass Growth: Ethanol \rightarrow Biomass	$r_{^{13}\text{C-DIC}} = P r_{\text{ED}} \frac{[\text{ED}_n]}{[\text{ED}_i] + [\text{ED}_n]} (\epsilon_{\text{ED/DIC}} + 1)$	<u>Denitrification</u> +8 ‰ (Rodríguez-Escales et al., 2014) <u>Sulfate Reduction</u> +1.8/-19.1 ‰ (Goevert and Conrad, 2008)
Biomass Decay: Biomass \rightarrow DIC	$r_{^{13}\text{C-DIC}} = R[X]b$	0 (Rodríguez-Escales et al., 2014)
Calcite Precipitation: DIC \rightarrow Calcite	as Mook et al. (2004)	calculated from van Breukelen et al. (2004) and Mook et al. (2000) considering a temperature of 15°C: $\epsilon_{a/b} = 10.12$ ‰; $\epsilon_{c/b} = -0.49$ ‰; $\epsilon_{c/b} = +0.41$ ‰ (where a is CO_2 , b HCO_3^- , c CO_3^{2-} and s CaCO_3)

Table 3[Click here to download Table: 2-Rodriguez-Escales_TABLE 3_v2_r1.docx](#)

Table 3. Concentrations of the aquifer and the injection solution used for the model.
Data from Vidal-Gavilan et al. (2013).

Parameter	Unit	Aquifer solution	Injected solution
		Value	Value
Ethanol	mM		13.7
Nitrate	mM	2.0	2.0
DIC	mM	9.5	9.5
pH		6.7	6.7
Temperature	°C	15	15
Chloride	mM	1.4	1.4
Sulfate	mM	1.0	1.0
Calcium	mM	4.6	4.6
Sodium	mM	2.2	2.2
Magnesium	mM	1.4	1.4
Potassium	mM	2.4	2.4
$\delta^{15}\text{N-NO}_3^-$	‰	16.2	16.2
$\delta^{18}\text{O-NO}_3^-$	‰	8	8
$\delta^{13}\text{C-DIC}$	‰	-11.8	-11.8
$\delta^{13}\text{C-Ethanol}$	‰		-30.5

Table 4[Click here to download Table: 2-Rodriguez-Escales_TABLE 4_v2_r1.docx](#)**Table 4.** Comparison of parameters between the batch scale and the field scale. (1) Rodríguez-Escales et al. (2014) (2) Nagpal et al. (2000).

	DENITRIFICATION		SULFATE-REDUCTION	
	Batch scale ¹	Field scale	Batch scale ²	Field scale
Y_h (mol C-biomass/mol C-ethanol)	0.7	0.7		1.0
Q (mol C-ethanol/ mol nitrate-sulfate)	1.9	1.9		7.5
K_{max} (mol C-ethanol/mol C-biomass d)	1.1×10^2	1.1×10^2	5.2×10^1	5.2×10^1
K_{sat} C-ethanol (M)	1.5×10^{-1}	1.3×10^{-1}	9.0×10^{-3}	1.3×10^{-1}
K_{sat} nitrate (M)	1.7×10^{-4}	1.4×10^{-5}		
K_{sat} sulfate (M)			8.5×10^{-3}	5×10^{-3}
b (d^{-1})	0.15	0.95	-	0.95
K prep ($M d^{-1}$)	8.6×10^{-6}	4.3×10^{-4}
