**Abstract**—A quick-scan yield prediction method has been developed to assess rooftop photovoltaic (PV) potential. The method has three main parts. For each roof, first (i) virtual 3D roof segments were reconstructed using aerial imagery, then, (ii) PV modules were automatically fitted onto roof segments using a fitting algorithm and finally, (iii) expected annual yield was calculated. For each roof, the annual yield was calculated by three different quick yield calculation approaches. Two approaches are commercial software packages of Solar Monkey (SM) and Photovoltaic Geographical Information System (PVGIS) whereas the other one is the simplified skyline-based approach developed in photovoltaic material and devices (PVMD) group of Delft University of Technology. To validate the quick-scan method, a set of 145 roofs and 215 roof segments were chosen in urban areas in the Netherlands. For the chosen roofs, the number of fitted modules and calculated yield were compared with the actual modular layout and the measured yield of existing PV systems. Results showed a satisfactory agreement between the quick-scan yield prediction and measured annual yield per roof, with relative standard deviations of 7.2%, 9.1%, and 7.5% respectively for SM, PVGIS, and PVMD approaches. It was concluded that the obstacle-including approaches (e.g. SM and PVMD) outperformed the approaches which neglect the shading by surrounding obstacles (e.g. PVGIS). Results also showed that 3D roof segments had added value as input for the quick-scan PV yield prediction methods since the precision of yield prediction was significantly lower using only 2D land register data of buildings.

**Index Terms**—automatic PV system design, annual energy yield, module fitting, PV potential, PV systems, quick-scan, rooftop PV, Urban PV, yield prediction.

## 1. INTRODUCTION

AS humankind feels daunted by the challenge to meet their energy demand in a more sustainable and fossil-free manner, the transition to renewable energy sources such as wind and solar has begun. In 2018, global annual photovoltaic (PV) installations were surpassed 100 GW, and the total cumulative operational capacity reached over 0.5 TW [1, 2]. Even though the prices of photovoltaic systems have decreased significantly over the last decades, the adoption of PV is not increasing rapidly [3]. The mindset of society must change towards PV and PV revolution [4]. Therefore, a more societal push is necessary to help the solar PV industry grow.

Such societal push could be supported by automatic PV system design in various ways. First of all, the time required to design a PV system could be decreased considerably. Ranging from software-aided design to visual in-situ inspection (e.g. counting the number of roof tiles to have a rough estimation of roof PV potential), the actual design of a rooftop PV system may take anywhere from 10 minutes to several hours [5][6]. Because of the fierce competition in the domestic PV system market, only a small percentage of the designs are built. Much time could thus be saved on the side of the PV installation companies if the system designs on their quotations are generated automatically. An automatic PV system design can also make the sales process of PV more efficient. It would decrease the effort and time spent by cold-calling potential customers. The activity of the whole solar energy market could increase as a result of a more efficient sales process since it would increase productivity. Moreover, an advanced design algorithm could design systems with more accurate energy yields, better aesthetics or better cost-effectiveness than humans could do manually in the same amount of time. The optimal

41 position for modules could be calculated, minimizing the shading throughout the year. Additionally, algorithms could find  
42 alternative module configurations that would fit more modules on the same roof. For example, it could find a balance  
43 between the yield per m<sup>2</sup> and total yield by comparing east-west or south-directed setups according to the customer's  
44 requirements. From another point of view, by facilitating yield prediction and system design in a quick and user-friendly manner,  
45 consumers would have fewer concerns about the suitability of their rooftop for a PV system.

46 To fulfill this goal, a so-called *quick-scan* yield prediction method was developed. The method fully automates the design  
47 process and yield prediction of rooftop PV systems. It also enables large-scale rooftop PV potential assessments (e.g. a city or  
48 a district) by reducing the runtime as much as possible. This paper aims to introduce the quick-scan method and discuss the  
49 findings regarding the following research questions: (1) how realistic is automatic module fitting on residential rooftops? (2)  
50 how accurate is yield prediction with different quick yield calculation approaches? (3) How fast are different parts of the quick-  
51 scan method and how can this be optimized?

52 Section 2 gives an overview of relevant literature about the estimation of solar potential for rooftops in urban areas and  
53 briefly explains the research outline. In Section 3, the different parts of the quick-scan method are described. Section 4 shows  
54 the results of the module fitting algorithm and yield calculation approaches and discusses the simulation time. Lastly, conclusions  
55 will be drawn in Section 5, and recommendations will be presented for future work.

## 56 2. LITERATURE REVIEW AND RESEARCH OUTLINE

57 The potential of buildings for rooftop PV is usually determined by (i) finding the available roof area for PV modules, (ii)  
58 simulation of plane-of-array (POA) solar irradiance and, (iii) computing the annual AC energy yield of such system.

59 Land use, building and population densities can be used to calculate the total roof area using average conditions, and the  
60 available roof area for PV can then be found by assuming fixed utilization factors [7]. In 2010, Winginton et al. used the  
61 relation between roof surface area and population to estimate the rooftop PV power generation potential for Southeastern  
62 Ontario, US [11]. Similarly, the solar energy capacity was analyzed for different types of residential rooftops in Andalusia,  
63 Spain [12]. In 2012, Defaix et al. published the building- integrated photovoltaic (BIPV) potential for 27 European member  
64 states, starting from an average floor area per capita to find the available roof surface per country [13]. For the Indian city of  
65 Mumbai, aerial images were used to calculate values of the Building Footprint Area (BFA) ratio and the Photovoltaic- Available  
66 Roof Area (PVA), to estimate the city's PV potential [14]. An earlier Indian investigation of Delhi's PV potential was based on  
67 thumb-rules, standard assumptions and experts' opinion, due to data unavailability [15]. In 2014, Mainzer et al. analyzed the  
68 technical PV potential for each municipality in Germany, estimating the usable area and energy demand per building by  
69 statistical data [16]. In 2015, Byrne et al. calculated the net usable roof area per building type for Seoul (South Korea),  
70 including a parametric study of the module tilt and its effect on the Ground Cover Ratio (GCR) and expected PV potential of  
71 the city [17]. In 2017, Khan et al. carried out a similar study for 13 cities in the Kingdom of Saudi Arabia, and the potential  
72 electricity generation was estimated [18].

73 Other methodologies based on geographic information system (GIS) has increasingly used recently, particularly since GIS has  
74 become a commonly used tool [8]. If available, GIS data of the outer shapes of buildings can be used to estimate the available  
75 roof area. In 2011, the potential electricity production by rooftop PV in Israel was assessed, by using GIS data of outer  
76 building shapes and making assumptions about utilization factors [19]. Martín-Chivelet proposed an analytical expression for  
77 GCR and a step-by-step methodology for the assessment of PV potential [9]. In 2015, Freitas et al. provided a review of solar  
78 potential calculation methods for urban areas and concluded that methods should compromise between accuracy and computation  
79 time [10].

80 If also 3D information and/or height data is available, such as LiDAR measurements, the pitch angle, and azimuth of

81 roof segments can be used to determine the POA irradiance. In 2012, Brito et al. used LiDAR data to assess the  
82 photovoltaic potential in a Lisbon suburb [20]. It was concluded that for PV penetration below 10% of the total roof area,  
83 the PV potential can be well estimated by neglecting shade and considering the optimal inclination and orientation for PV,  
84 whereas, for high penetration, the potential can be estimated by considering a horizontal surface within the building footprint  
85 area. In 2011, Bergamasco et al. assessed the PV potential for rooftop-integrated PV systems using MATLAB, first by a study  
86 in the Piedmont Region [21]. Later, the MATLAB algorithm was enhanced with shadow and in-roof obstacle detection and  
87 applied to the city of Turin, processing over 60,000 buildings [22]. In 2013, Kodysh et al. combined LiDAR data and a GIS  
88 approach to estimate irradiance on different roof surfaces for Knox County, Tennessee, USA [23]. The output of the study was  
89 however solar irradiance per roof surface area since the available area for PV and electricity output were out of the scope  
90 of the research. In 2014, the rooftop PV potential of Taiwan was assessed, using GIS data for the available roof area and  
91 taking into account shading caused by other buildings [24]. There are some examples in which 3D city models are used  
92 to calculate the total roof area and expected electricity generation, such as the work of Rodriguez et al. for Ludwig- burg,  
93 Germany [25]. However, 3D city models are expensive to create or acquire, and currently unavailable for most regions in the  
94 world. Moreover, shading calculations with 3D models and ray-casting are computationally demanding and, therefore, restrict  
95 the scale for which the PV potential can be determined.

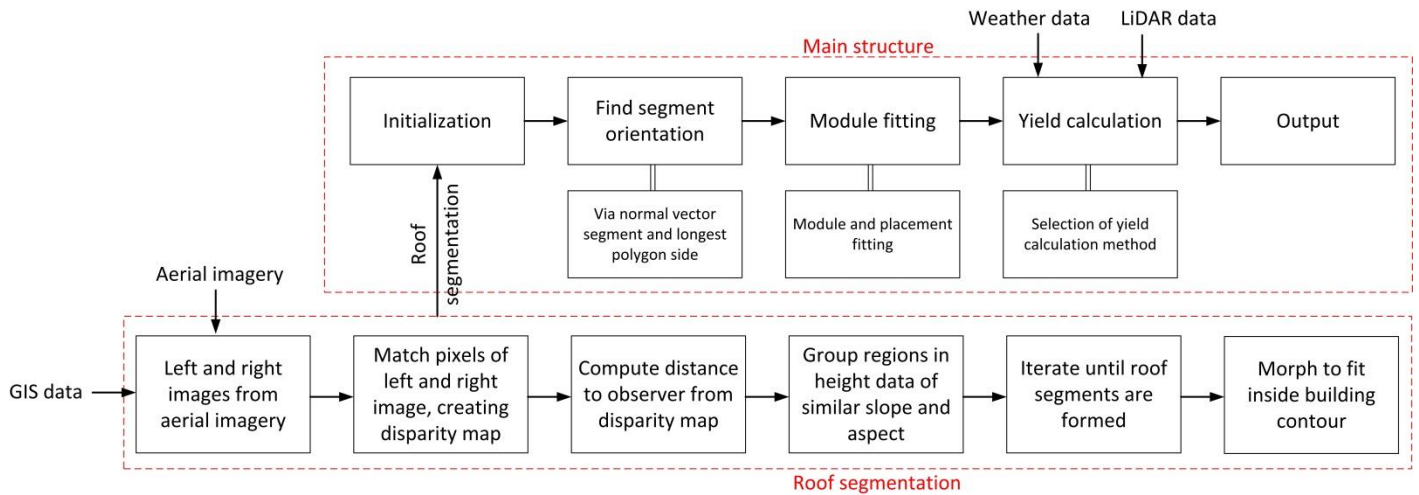

96 Some of the studies described above calculate the discrete amount of PV modules to be placed on the available roof area by  
97 GCR factors, however, none of them computed the actual modular layout that would fit on each roof segment. The only  
98 exception to that is a research carried out by Mainzer et al. in 2017 in which geographical building data and aerial images in  
99 combination with image recognition techniques were utilized to virtually place modules on roofs [26]. Their module fitting  
100 algorithm incrementally iterates over the usable area and fits as many PV modules as possible within each roof segment.  
101 However, it neglects a distance to be taken from the roof edge and module alignment with the edges for flat roofs.

102 For simulation of POA irradiance and computing the annual AC energy yield, various levels of detail could be applied in  
103 yield calculation models. For example, skyline profile (the outline of land and buildings around a PV system defined against the  
104 sky) affects the amount of solar irradiance that reaches a PV module [27]. Although shading reduces the PV module  
105 performance [28], in yield prediction approaches, the skyline profile is usually not determined for each roof, neglecting the  
106 shading caused by it. More advanced yield calculation models including non-linear effects of temperature, module  
107 technology, and inverter utilization significantly increase the runtime and fairly improves the accuracy [26]. However, when  
108 dealing with a big batch of roofs, both *accuracy* (closeness of a dataset, in this case the modelled PV yields, to the perfect  
109 prediction line on which the modeled and measured kWh/kWp values are the same) and *precision* (closeness of a dataset, in this  
110 case the modelled PV yield, to their own average kWh/kWp line) are important.

111 Real-life situations can lead to systematic and random errors in PV modeling. Systematic errors shift away the modeled data  
112 points from the perfect prediction (reference) while random errors cause the modeled data points to be scattered. Systematic and  
113 random errors respectively relate to accuracy and precision. For large scale studies or initial investigation (quick-scan) of a batch of  
114 rooftops, precision is as important as the accuracy. The reason is, obtaining precision is way faster than accuracy and needs less  
115 inputs and/or detailed modeling and, when a precise batch of output data for PV potential of rooftops is found, then all the results  
116 can be shifted (tuned) by a simple (and fast) correction factor to have both precise and accurate batch of output data. Therefore, the  
117 aim of this research is to develop a method that can quickly scan the PV potential of many roofs with high precision and, then,  
118 further modify it by a correction factor to have also an accurate result dataset. It is worth noting that applying one correction factor  
119 to all the yield predictions will improve several individual PV systems yield prediction while it might worsen the yield prediction  
120 of a few. However, the overall prediction for all the PV system will improve.

121 The method developed in this research uses 3D roof segment data, generated from aerial images and GIS data, to assess the

122 discrete number of PV modules to be fitted on each roof. The module fitting is tested by selecting buildings that already have  
 123 PV systems on their roofs and comparing results to the number of modules that were actually placed. Also, LiDAR height data  
 124 is used to account for the effects of shading by surrounding obstacles. The precision of three different yield calculation  
 125 approaches is obtained using AC yield measurements of real PV systems. The developed method tries to keep the calculation  
 126 time as low as possible, in order to make the algorithm usable for rooftop PV on a regional or national scale.

127  
 128 Fig. 1: The general structure of the quick-scan method. Flowchart of roof segmentation using aerial imagery feeds the quick-scan method.  
 129 Weather, GIS, and LiDAR data were also used as inputs to the quick-scan method.

### 130 3. METHODS

131 In figure 1, general structure of the quick-scan algorithm is shown. To initialize, a set of roofs divided into 3D roof segments  
 132 is fed into the algorithm. For each segment, the segment orientation is calculated, making use of two independent methods.  
 133 Then module fitting is carried out, to find the maximum amount of modules that can be placed on them. For the solution  
 134 accommodating most modules, yield calculation is carried out per roof segment. Finally, the output of the quick-scan algorithm  
 135 will be the number of fitted modules, their expected annual AC yield in kWh and the specific annual yield kWh/kWp, each  
 136 aggregated per roof or physical address. Prior to PV system installation, the widely used merit by the industry and research  
 137 communities is either kWh or kWh/kWp, which give indications on how much the PV system will yield. However, after  
 138 installation, to monitor the difference between the expected and the real PV yields, the merit performance ratio (PR) is used.  
 139 Since the target of this research was yield assessment of the roofs, kWh and kWh/kWp were used as merits.

#### 140 3.1. Roof segments extraction

141 In order to develop a quick-scan that works for any address, it is necessary to have information about the roofs: roof area (for  
 142 PV module fitting), its slop and orientation (for yield prediction). One way is to use land register data of the buildings contours  
 143 which is accessible in several countries. However, most roofs do not consist of one flat plane and have obstacles which are not  
 144 detectable in buildings contours. In this research, roofs are divided into segments with different slope and orientation using  
 145 stereo aerial images. The algorithm is shown in the lower part of figure 1. A roof is selected by using the building contours from  
 146 land register data for the target building. A disparity map is made by matching the roof pixels of a pair of aerial images taken  
 147 from a different angle (stereo-matching in GIS [29][30]). A 3D point cloud is then obtained by comparing many points on a  
 148 roof, as shown by a disparity map in figure 2.

149 Since different segments have different orientations and pitch angles, their colors are slightly different in an aerial image. In  
 150 order to split the roof into different segments, a first segmentation is carried out on the basis of color. This color filtering

151 creates a large number of small segments, as visible in the left part of figure 3. After this, the height data is used to unify  
152 segments with similar orientations, pitch angles and heights. These orientations and pitch angles are found by calculating the  
153 normal vectors of the planes that form the segments. The remaining segments form a 3D representation of the roof segments  
154 and potential obstacle segments like chimneys or roof windows. This process is shown in figure 3 and described in further  
155 detail in [30].

156 Small roof segments and segments that are on the shadow side of an aerial image are more difficult to detect. This is  
157 caused by a lack of height data points for small segments, and little contrast to find a stereo-pair of pixels in the shade. Also,  
158 the difference in color at the borders of segments is harder to detect for shaded roof segments [31].

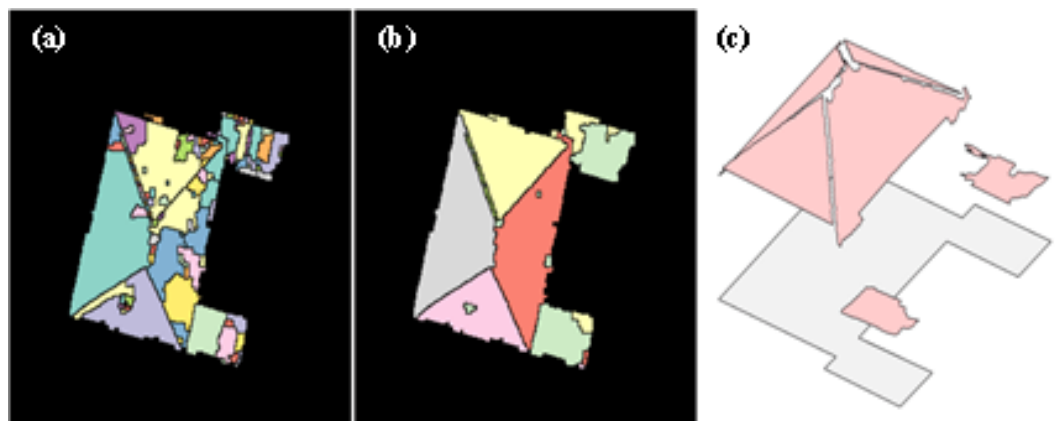

159 To make the segments cover a larger part of areas within building contours and to straighten the edges of roof segments,  
160 three additional steps were applied automatically to the roof segments:

- 161 1) For neighboring roof segments which intersect in 3D, such as for hipped roofs and gable roofs, the line of  
162 intersection between the planes was determined. The roof segments are filled from both sides up to this line.  
163 For neighboring roof segments that do not intersect, but have a height difference, a line of intersection is drawn in the  
164 middle when looking at them in the z-direction. The roof segments are filled from both sides up to this line.  
165 2) For the parts of roof segments that stretch to the edges of the building contour, the segment will be filled up to the edge of this  
166 land register shape.

167 In figure 4, a group of roof segments is shown. As it can be seen in figure 4, after applying the three aforementioned steps the  
168 edges of roof shapes are much straighter.

169  
170 Fig. 2: Images (a) and (b) represent a same roof from two slightly different angles. The two stereo aerial images are used to obtain a 3D  
171 point cloud for a roof, shown in a disparity map on figure (c), obtained from [30]. Black dots shows the parts of the roof where could not be  
172 fully re-constructed by the roof segment algorithm. Since the difference in angle between the two images is known, the displacement of a point  
173 between the two images is solely dependent on the height [30].

174

175  
176  
177  
178  
179  
180

Fig. 3: Image (a) shows several small segments that are constructed based on their color in the aerial image. In image (b), to form the neat roof segments, adjacent small segments were unified based on their orientation, pitch angle, and height. In image (c), the roof segments are shown in 3D projected above the building contour, obtained from [30].

The orientation of a roof segment was determined by taking the horizontal projection of the normal vector to the segment plane. However, this orientation determination approach might cause an error for flat roofs. Therefore, an alternative approach for orientation determination was developed.

181  
182  
183

185  
186  
187  
188  
189

Fig. 4: Aerial image and roof segments, created before (left) and after (right) three straightening steps were applied. The small mismatch between the edges of the roofs and the segments is caused by the fact that the aerial image was not taken at exactly  $90^\circ$ . Since the segmentation of the roofs is dependent on the building contours, the contrast and the colors in the aerial image, sometimes segments contain flaws: (1) shaded roof segments are rarely detected. This is often a problem for low flat roofs next to taller houses. (2) sometimes existing roof segments are not detected because they were outside of the land register perimeter. This could be because of a recent house renovation or outdated land register data. Garden sheds, garages and building extensions can be overseen for this argument. (3) sometimes obstacles are detected or left out of the roof segments by the stereo-matching, either excluding from all segments or forming separate roof segments.

190  
191  
192  
193  
194  
195  
196

Throughout this research, roof segments with a slope of less than 10 degrees were categorized as flat, and segments with a higher slope were considered pitched. This boundary was chosen based on architecture and building construction industry [32], as no scientific studies were found to set this variable differently according to PV standards.

The length of each line segment was determined for the x and y coordinates, and then the longest side of the polygon within the roof segment, the longest polygon side, was chosen. For the longest polygon side, the orientation can be determined by the following equation:

$$A_{ls} = \tan^{-1} \left( \frac{x_2 - x_1}{y_2 - y_1} \right) + 180^\circ, \quad (1)$$

198 where  $A_{ls}$  stands for the azimuth of the longest side,  $x_i$  and  $y_i$  refer to the x and y coordinates the points on the roof  
199 segment.  $180^\circ$  is added to make the angle positive, defined clockwise starting from the North direction.

200 The modules alignment with the roof segment orientation is preferred since it usually fits the largest number of modules and  
201 often regarded to be more aesthetic. Figure 5 shows an example in which 33% more modules can be fitted for an aligned  
202 setup, whereas the output per module would only drop 0.5% due to the less favorable orientation (20 degrees off south, the tilt

203 was 13°).

204 Having the azimuth of one edge and knowing that most roof segments have rectangular shapes or perpendicular angles, one  
205 can obtain the azimuth of the other three edges for flat roofs:

$$206 \quad B_i = A_{Is} + \sum_{i=1}^3 i \cdot 90^\circ, \quad (2)$$

$$207 \quad \begin{cases} A_i = B_i & B_i < 360^\circ \\ A_i = B_i - 360^\circ & B_i \geq 360^\circ, \end{cases} \quad (3)$$

208 where  $i = 1, 2$  and  $3$ , so  $A_i$  are the three orthogonal components to  $A_{Is}$ , which are always between  $0^\circ$  and  $360^\circ$ , ensured by the  
209 constraints in equation 3. From here, the direction closest to the South ( $180^\circ$ ) will be chosen as the module orientation for all  
210 flat roof segments.

### 211 3.2. Maximum module fitting technique

212 A fitting algorithm was developed and implemented to place the maximum number of PV modules on top of a roof. The  
213 following input settings were chosen:

- 214 • Module dimensions of  $165 \times 99$  cm<sup>2</sup> and the rated power of 300 Wp were chosen. The thickness of the modules is not of  
215 interest to the quick-scan.
- 216 • For flat roof segments, all modules were expected to be installed in a landscape manner with a fixed and tilt and row space  
217 (most dominant layout on flat roof).
- 218 • For pitched roof segments, the module is placed directly onto the segment. There is no row distance between modules. The  
219 module layout can be either in portrait or landscape, and both options are investigated to find the maximum module configuration.  
220 Thus, for all pitched roof segments, the fitting algorithm is carried out twice (one for portrait one for landscape).

221 Description of maximum module fitting technique is as follows. After defining the input settings, first, a rectangular module grid  
222 is created according to the settings specified for flat and pitched roofs. Then, the module grid, in this case with zero row  
223 distance, is shifted in the x and y directions. The step size was set to 10 cm in both directions, as recommended in [34].  
224 Further, for every new position of the grid, the number of modules within the roof shape minus a set distance from the edge  
225 is counted. Finally, the position in which most modules are fitted gives the maximum module fitting solution. For a simple  
226 case of PV modules with zero tilt, a visual impression is given in figure 6. Details of several approaches for module fitting  
227 on roofs were discussed in [34].

228 By automatically defining obstacles as gaps in a roof segment, they can be avoided for module placement. The algorithm  
229 always checks if modules are intersecting obstacle segments. Roof segment are not always aligned with the x and y axes of the  
230 module grid. Therefore, a roof segment is automatically rotated around its center to match to the desired azimuth of the  
231 modules. Then the module grid is created. After this step, the roof shape and module grid are rotated back and the grid is  
232 translated in steps parallel and perpendicular to the module azimuth. For flat roofs with tilted modules, the row distance is  
233 inserted in the grid between the rows of modules. Figure 7 visualizes an example for the module fitting algorithm compared  
234 with manually fitted modules showing the possibility for different results caused by shape flaws in roof segments or in-roof  
235 obstacles.

243

244

245

246

Fig. 5: Aligned with roof (left) vs due south module layouts for flat roof (right), adapted from [33]. It is worth noting that, from energy yield point of view, alignment of the PV modules with the roof edges is influential only for the case of the flat roofs because pitched roofs already have a fixed azimuth and tilt which PV module should comply with (mainly because of wind force and safety reasons). In general, the lower the tilt of the PV modules on a flat roof, the less influence of azimuth deviation from the true South. Besides energy yield, factors such as accessibility, cost, and aesthetics also play a role on the decision of PV modules azimuth on a flat roof.

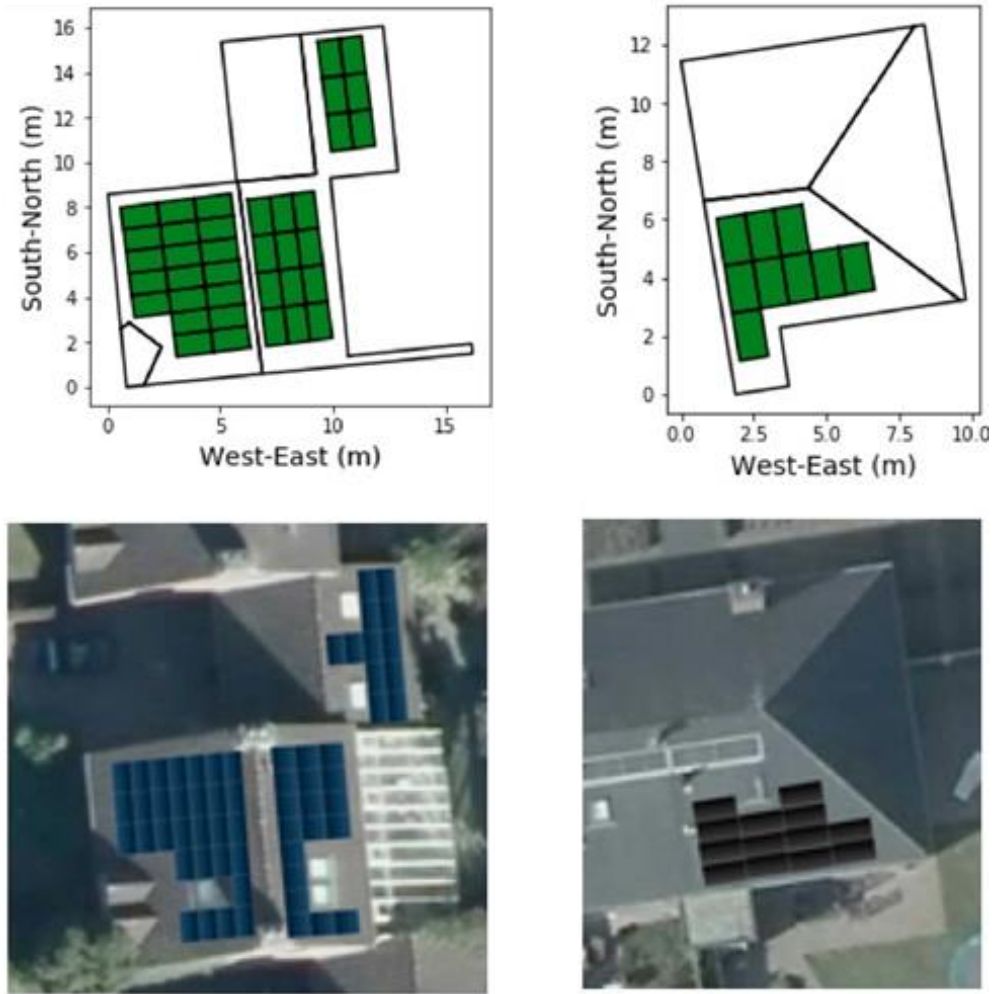

247

248

249

250

Fig. 6: A module grid (rectangular shape) is superimposed over a roof (polygonal shape) and moves around in the x and y directions, while counting the modules that fit within the roof edge minus a buffer distance without intersecting with obstacles, obtained from [34]. The figure is a screen shot of one moment of running the maximum module fitting technique.

251

252 Fig. 7: Aerial images with manually placed PV modules (bottom) and corresponding visual schematics (top) of fitted modules by the  
 253 algorithm, showing that module setup can yield different results due to (1) shape flaws in roof segments, and/or (2) in-roof obstacles,  
 254 and/or (3) different size and orientation of the modules, and/or (4) difference in edge-distance considerations.

260

261

262

263 Fig. 8 (a): Schematic view of row distance between modules, (b): Counts of row spaces for installed PV systems on flat roofs which shows  
 264 that the dominant row spacing in the database of Solar Monkey in the Netherlands is  $70 \pm 5$  cm, and (C): Counts of PV systems with similar tilts  
 265 shows that three dominant tilt angles  $10 \pm 0.5^\circ$ ,  $13 \pm 0.5^\circ$  and  $15 \pm 0.5^\circ$ . We chose 13 degrees as an average. It is worth noting that in an elegant  
 266 PV system design, the row distance should be set based on the desired shade-free window, ground coverage ratio requirement, and the shadow  
 267 length equation. In reality, however, installers use quick fixed row distance values for the Netherlands mainly driven by the two facts: (1) the  
 268 tilt should be kept low because of high wind force in the Netherlands, and (2) shadow has less effect because of high share of the diffuse  
 269 component in the sunlight in the Netherlands.

270 **3.3. Yield calculation approaches**

271 The quick-scan was designed in a modular way, so different energy yield calculation approaches can be applied and their  
 272 results can be tested independently. Three yield prediction methods were investigated in this research: the first method used in  
 273 this study was developed by Photovoltaic Geographical Information System (PVGIS), the second method is based on the current  
 274 approach of Solar Monkey (SM), and the third method is developed by the Photovoltaic Materials and Devices (PVMD) group of  
 275 Delft University of Technology [27].

276 In the PVGIS yield calculation method, the skyline profile is not taken into account. In PVGIS website, only the module  
 277 orientation and tilt are affecting the performance. The other methods do use the skyline profile. SM approach calculates a skyline  
 278 profile (or obstacle view) for every PV module that is placed on a roof. For the quick-scan, this obstacle view is only calculated  
 279 for one point at the center of each roof segment. The height of this point is chosen as the highest of two height data sources. One  
 280 source is the digital elevation map at the building location obtained by LiDAR, and the other source is the collection of z-  
 281 coordinates of the roof segments found by stereo-matching. By taking the highest of both sources, situations are avoided where  
 282 the central point is located slightly below the actual roof surface, resulting in extremely high obstacle losses. The PVMD yield  
 283 prediction method is implemented according to how it was explained in [27]. PVMD approach uses two coefficients: Sky View  
 284 Factor (SVF) and Sun Coverage Factor (SCF), respectively to indicate how much of the hemisphere is freely visible and the ratio

of hours that the sun is blocked with respect to the total amount of sun hours. For every climate, having the SVF and SCF, the yearly energy yield can be estimated using five fixed coefficients. The coefficients depend on the azimuth and the tilt angle of the PV module. In this research, these five coefficients were calculated for every 10° azimuth and tilt angle (and linearly interpolated for the degrees in between).

#### 4. RESULTS

To test of the proposed method, a dataset of several buildings located in the region of Eindhoven, the Netherlands, was chosen. The chosen buildings have monitored PV systems on their roof. The roof segments are extracted as polygons, containing 3D coordinates of the edges for each roof segment. Each roof is marked with a unique building identification (id), linked to the land register data for each building in the Netherlands. Additionally, each identified roof segment is given a unique number. Besides the coordinates and id's, the segment slope (pitch angle) and azimuth (orientation in a horizontal plane) are given. The numbers of investigated roof segments for each part of the quick-scan method are shown in Table I. For the roof segments extraction, roofs were selected randomly whether they had PV module on top or not. For maximum module fitting technique, only roofs that had PV systems on top were manually selected. For annual yield prediction, only roofs with PV system that had reliable measured energy yield were manually chosen.

To check the performance of the quick-scan algorithm, the results of module fitting were compared to the actual amount of modules placed on a set of roofs with existing PV systems. Then, the results of yield calculation were compared to the measured energy yield of the PV systems in their first operational year.

TABLE I: Numbers of studied roof segments for each part of the quick-scan method.

Parts of the method	No. of roof segments
Roof segments extraction	520
Maximum module fitting technique	215
Yield calculation approaches	156

##### 4.1. Input data

Extraction of 3D roof segments can be done by either LiDAR data or aerial imagery. LiDAR datasets are relatively expensive to gather compared to aerial imagery [35], usually less frequently updated, and not as widely available as stereo imagery. For the Netherlands, a countrywide LiDAR dataset, *actual hoogtebestand Nederland* (AHN), with the ground resolution of 50 cm exists and has been updated almost every seven years [36]. As an alternative to LiDAR data, a countrywide aerial stereo imagery (Stereo10) is available at a ground resolution of 10 cm for the Netherlands. Imagery is retrieved every year; mostly during winter and early spring, when the weather condition is good. The aerial imagery of geographical area considered in this paper is captured by an ultracam xp camera. Imagery was gathered from an altitude of 1600 m, taking into account variations in roll, pitch, and yaw of the camera, which is mounted to the airplane. Since aerial imagery has a resolution of 10 cm, the point-cloud retrieved from image matching has a density of 100 points/m<sup>2</sup>. This is denser than the 6-10 points/m<sup>2</sup> of the AHN (LiDAR data). Therefore, in this research aerial imagery was used for roof extraction while LiDAR data was used for reconstruction of the horizon around the roofs. Besides, for the target geographical area, the data from network of weather stations in the Netherlands, known as *Koninklijk Nederlands Meteorologisch Instituut* (KNMI), was used as input for PV yield calculations [37]. Depending on the KNMI station, the availability of ambient parameters and their resolution might be different. In this research weather data with the resolution of one hour was used.

## 4.2. Roof segments

On average, it takes one-fourth of a second (0.257 seconds) to reconstruct the roof segments of a residential building. Within the studied set of roofs, 93% of the roof segments larger than 1 m<sup>2</sup> were detected.

The approach described for finding the segment orientation was tested for a set of 520 roof segments, using the orientation given in the data set as a reference. For pitched roofs, with a roof pitch higher than 10°, the deviations between the two sources of segment orientation are generally small. The absolute error was found to be within 6.3° for 95% of the pitched segments. All 28 pitched segments with an error higher than 5° were inspected manually to find the true orientation of the roof segment. Only for pitched segments with deviation values above 16° the method was found to be inaccurate. For these cases, in 7 out of 10 segments the algorithm found a wrong edge (as the closest one to the South). This was caused by segmentation errors or non-rectangular roof segment shapes.

## 4.3. Module fitting

First, in module fitting technique, the tilt and row distance should be set (see figure 8(a)). A tilt of 13° was chosen for modules because this is a common setting for mounting PV modules in the Netherlands as low module tilt reduces ballast requirements and increases the roof area utilization (see figure 8(b)). A distance of 70 cm was maintained as the horizontal distance between the projected end of a tilted module and the front side of a consecutive row (see figure 8(c)).

A visual inspection was carried out for 215 roof segments (total 145 roofs) by comparing recent aerial images with the roof segments. The segments on which PV modules placed were added to a list of manually selected roof segments. In this way, the module fitting algorithm and yield estimation approaches were tested more precisely. The following three roof groups were detected:

- (group 1) 104 segments were fully used for PV installations. The maximum number of modules was placed on these segments.
- (group 2) For 66 roof segments, almost two-thirds of the surface were used. The most common reason was that obstacles within the segment were not detected in aerial imagery. Sometimes, the building owner had no desire to use the full potential of the roof, or choose for a rectangular (aesthetic) module layout instead of fitting the maximum amount of modules.
- (group 3) For 45 roof segments, almost one-thirds of the surface were used. The most common reason was that the building owner had no desire to use his entire roof for PV. However, in twenty cases very large obstacles or a multitude of them were not detected.

Visual inspections showed that assessing the performance of the module fitting technique can be affected by individual choices of house owners. To compensate for this effect, for the second and third roof segment groups, the number of fitted modules by the algorithm was manually multiplied by 2/3 and 1/3, respectively (as manual module placement ratios). Although it was possible to divide the roofs into more than three groups (to have more accurate compensation for roof owners' choices), the three groups gave satisfactory results while saving the time.

The results of module fitting technique, shown in figures 9 and 10, reveals that the module fitting algorithm generally fits fewer modules on roofs than the real number of installed PV modules. The module placement was underestimated by 17.5% on average, with a relative standard deviation (RSD) of 46.3%. There could be multiple reasons for this under-estimation:

- Shape flaws in the roof segments mainly caused by over-segmentation (the algorithm mistakenly identifies more roof segments within a roof than what it is in reality) is the first reason. Additionally, parts of roof segments in the shade were not occasionally detected by the stereo-matching, decreasing the available area for modules to be placed.
- The categories of module placement ratios were set manually by looking at low-resolution images, which might have caused mistakes.

359 • The algorithm settings for module layouts could be different from reality. Smaller PV modules, lower module tilt on flat roofs  
 360 and, therefore, smaller row distances might have been chosen by the installers. These options were not investigated in further  
 361 detail.

362 An average module fitting time of 1.01 seconds per roof segment was found, with a standard deviation (SD) of 1.08s. Since  
 363 the time per roof is strongly dependent on the segments within a roof, the module fitting time per roof was not analyzed further.  
 364 The large standard deviation in module fitting time per segment comes from the wide variety in segment area within the data  
 365 set, and the difference in module fitting time between flat and pitched segments (for pitched roof segments, the fitting  
 366 algorithm is carried out twice, refer to Section 3.3). The module fitting speed was 30.4 (SD=18.2)  $m^2s^{-1}$ . The module fitting  
 367 speed for pitched roofs without internal obstacle segments was 20.1 (SD=5.0)  $m^2s^{-1}$ , whereas the module fitting speed for  
 368 flat roofs was 56.9 (SD=12.0)  $m^2s^{-1}$ . For flat and pitched roofs, the module fitting time per segment are shown in figure 11.  
 369

370 **4.4. Yield calculation**

371 After having the roofs automatically filled with PV modules, the specific annual yield is calculated for each roof segment  
 372 and compared with measured data of installed PV systems. As discussed in Section 2, only the *precision* of three yield  
 373 calculation approaches is evaluated. This was decided since with a large batch of roofs, the average offset in *accuracy* in yield  
 374 estimation can quickly be corrected by a multiplication factor, as long as desirable precision is achieved. In this research, after  
 375 running the quick-scan (panel fitting plus yield calculation) for all roof segments and obtaining the result dataset, the precision of  
 376 the dataset is calculated. Then, the whole dataset is shifted by a single multiplication factor (1.0412) to be as close as possible to  
 377 perfect prediction (high accuracy). Although the modelling accuracy for a few PV systems might drop, the multiplication factor  
 378 improves the overall accuracy of the modelling. The results of quick-scan method for each yield prediction approach are shown  
 379 in Table II. Figure 12 shows the results for the SM yield calculation approach in a scatter plot with an RSD value of 7.2%.

380 TABLE II: Final results of the quick-scan per yield prediction approach, all roofs with pitched segments with orientation errors above 16°  
 381 were filtered out (resulting 132 roofs and 156 roof segments).

Yield prediction approach	SM	PVMD	PVGIS
Relative Standard Deviation	7.2%	7.5%	9.1%

384 It can be concluded that the SM method is marginally more precise than the PVMD method. The PVGIS method performs  
 385 significantly worse, which can be explained by the fact it does not take into account the skyline profile.

387 The calculation times of the yield prediction were found to be 6.93s (SD=0.56s), 6.50s (SD=0.44s) and 1.31s  
 388 (SD=0.21s) per roof segment for the SM, PVMD and PVGIS approaches, respectively. Since a real roof in the Netherlands  
 389 has an average of about 4 roof segments, the calculation times per roof required for SM, PVMD, and PVGIS would be in the  
 390 order of 28, 26 and 6 seconds, respectively. Since the calculation time per roof is very dependent on the number of roof  
 391 segments taken into account, the calculation speed could be greatly increased by filtering out low-potential roof segment  
 392 beforehand. A low-potential segment would not fit a significant amount of modules (e.g. less than 3) or is pitched towards the  
 393 North and, therefore, generates less than 650 kWh/kWp per year. By choosing a minimum segment area of 8  $m^2$ , and only  
 394 using pitched segments with an azimuth orientation between 75 and 285 degrees (South=180°), the calculation time per roof  
 395 could be halved without compromising the precision of the results. Further research can be done on the optimal boundaries  
 396 for such preliminary filtering.

397 For all yield prediction approaches, it was observed that the RSD increased for roofs with higher levels of shading, which is  
 398 caused by the fact that only one point per roof segment (middle point) was considered for obstacle detection. Additionally, shaded

399 segments have fewer data points that can be matched based on color recognition, such that the inaccuracy in segment  
400 orientation and pitch angle becomes larger. It was found that the three yield prediction approaches perform very similarly for  
401 roofs with an SCF below 0.25, however for roofs with a higher SCF the SM and PVMD approaches greatly outperform  
402 PVGIS because of neglecting the obstacle view by PVGIS.

403 For the SM yield prediction approach, the yield prediction accuracy and precision were analyzed for different sizes of roof  
404 segment. In this effort, the complication occurred that the performance could only be validated on roof level, while the yield  
405 prediction was carried out per roof segment. To overcome this, an average segment area was defined for each roof within the  
406 manual selection on which modules were placed. The average segment area per roof was a weighted average of the segment  
407 areas, by the amount of fitted modules, to reflect their contribution to the performance of the whole roof. For the full set of  
408 manually selected roof segments, the average roof segment area was 36.5 m<sup>2</sup>. The roof segments were categorized (based on  
409 size) into three groups of less than 25 m<sup>2</sup> (small), between 25m<sup>2</sup> (medium) and 70m<sup>2</sup>, and more than 70 m<sup>2</sup> (large). Figure 13  
410 shows the results for three categories of roofs, containing small segments, medium-sized segments, and large segments. The  
411 groups represent 35, 80 and 30 roofs, respectively. The results are described below:

- 412 • A high RSD is obtained for small roof segment group. The reason could be explained by the over-segmentation of several roof  
413 segments in the stereo-matching process. An over-segmentation of a suitable roof can lead to a smaller amount of modules fitted  
414 on it and, therefore, bias the yield prediction importance of a less suitable roof segment. Additionally, smaller segments contain  
415 fewer pixels in the point cloud and ,therefore, given values for roof pitch angle and orientation are less accurate.
- 416 • Medium-sized roof segments resulted in the highest accuracy prediction and the highest percentage of performance over-  
417 prediction. This over-prediction could be caused by unidentified obstacles within the roof segments, but also by the customer  
418 choosing not to use the best-performing segment, but place modules on a slightly lower-performance one.
- 419 • The most different result is found for the large roof segments. Their performance is generally under-predicted, while the RSD is  
420 highest with 11.7%. There could be multiple reasons for this. It might be that using one obstacle view is too inaccurate for large  
421 roof segments. A large roof segment could be divided in highly shaded parts and parts that are virtually free of any shade, so one  
422 reference point in the center might not be enough for obstacle view. Apart from that, large roof segments are seldom filled with  
423 modules. More often, it was encountered that they were only used partially. In this case, the installer would select the less  
424 shaded parts for installing PV modules. These decisions could make it difficult to test the improvement of performance  
425 prediction per roof. It would require selection of the part of a roof segment where PV was installed, either by manual  
426 inspection of aerial images or by pattern recognition of the PV modules through machine learning.

427 Here, two techniques are proposed to deal with large roof segments more accurately:

428 1) When the roof is large and more than a specific amount of modules is fitted, the PV array could be divided into multiple  
429 smaller parts. A boundary could be set at, for instance 10 modules or about 3 kWp, since this can be considered as the  
430 boundary for small residential systems. For each part of the module grid, a central point could be defined and thus the yield  
431 prediction could be done more accurately. An advantage of this techniques would be that the actual positions of modules  
432 are taken into account (not the middle of the roof segment). A disadvantage is that still a new method needs to be developed to  
433 erase modules from the system design.

434 2) Another method could be to divide large roof segments in smaller segments. For example a roof size of 33.4 m<sup>2</sup> could be  
435 chosen, since this was found as the average surface area of a roof which fits 10 modules. In this way, sub-segments with  
436 low performance could be discarded, and selection on high performance segments would then be possible. Parts of the roof  
437 could be considered independently. A big disadvantage of this techniques is that the sum of smaller segments cannot fit the  
438 same amount of modules as the full larger segment.

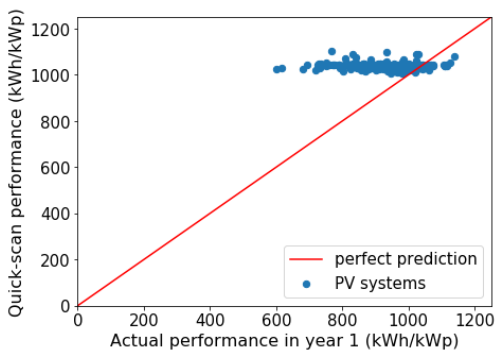

Fig. 14: Performance prediction using only land register data and no obstacle view.

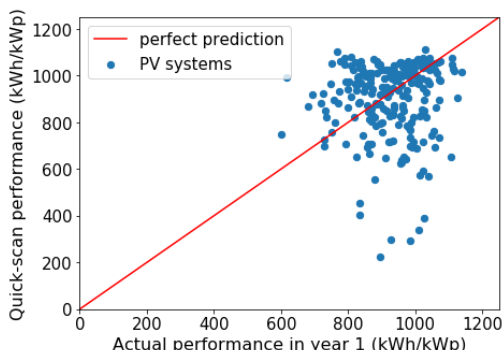

Fig. 15: Performance prediction using land register data and the obstacle view for the most central point on the roof.

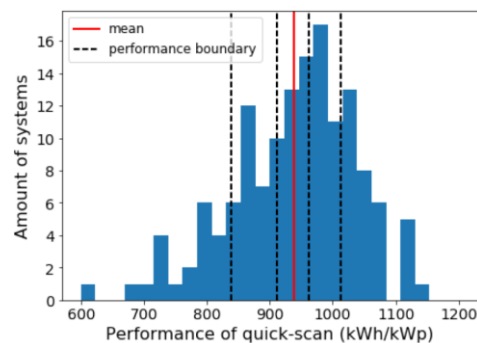

Fig. 16: Performance distribution for 236 PV systems installed in the Netherlands and being monitored.

#### 4.5. 2D Land register data vs. 3D roof segments

To show the added value of yield prediction with 3D roof segments over using land register data only, a similar test of yield prediction was carried out using only the latter. For yield prediction with only building contours, all roofs were expected to be one-segment and flat. With this assumption, the same module settings were used as for the flat roof segments.

In figure 14 the performance prediction can be seen, using the PVGIS yield calculation method neglecting the skyline profile. The quick-scan predicts an almost constant performance, since all roofs are supposedly flat, all modules have the same tilt, and no obstacles are taken into account. The lowest value found is 1030 kWh/kWp and the highest is 1114 kWh/kWp. The only deviations in performance are caused by the slight difference in module orientation due to alignment with the roof edges and the difference in landscape horizon height as given by PVGIS. In figure 15 the same performance prediction

477 is carried out with the SM yield calculation method. The predicted performance shows a wide spread of results. With 20.37%  
478 relative standard deviation this form of performance estimation is not useful. Therefore, taking the obstacle view from one central  
479 point on a roof with multiple segments is not a reliable method for determining the losses due to shading.

## 480 5. DISCUSSION AND CONCLUSION

### 481 5.1. Discussion and future work

482 Visual comparisons reveals that still there is a room for improvement for 3D roof segment reconstruction. For example, the  
483 uncertainty in the given pitch angle is unknown, and it is unclear how often over-segmentation or under-segmentation of roof  
484 segments takes place. Another common issue was that parts with obstacles within large roof segments were not defined as gap  
485 in those segments.

486 For large roof segments, multiple obstacle views can be considered. Advanced geometrical methods can also be used to  
487 calculate the parallax for nearby and far obstacles. Parallax refers to the geometrical translation of shading objects over the  
488 horizon for different points on the roof. Thereby multiple obstacle views can be created from skyline profile retrieved for the  
489 center of the roof (this would be easier if the horizontal distance from obstacles to the roof is known).

490 The maximum module fitting algorithm could be further validated by manually choosing the same module fitting settings  
491 (layout, distance, and tilt) as used in the installed PV system. It could be investigated if the quick-scan is more accurate for  
492 flat or pitched roofs of the same size. This question remained out of the scope of the current research. It is however expected that  
493 the quick-scan would be less accurate for flat roof segments, since a larger variability was observed in the settings for  
494 module layouts (e.g. tilt angles of 0° to 20° and, therefore, very different row distances). Moreover, the boundary between flat  
495 and pitched roofs could be tuned further by inspecting many more PV systems on the roofs with the pitch angle of 5° to 15°.

496 The quick-scan calculation speed can be increased in various ways. The two most time-demanding steps of the calculation are  
497 the module fitting technique and creating the skyline profile from the surrounding height data. To make the module fitting  
498 technique faster, an analytical approach could be implemented for rectangular roofs, as mentioned in [34]. Fine-tuning the step  
499 size for shifting the module grid can also be investigated. Loading of height data and the calculation of obstacle views can  
500 be made faster through recommendations highlighted in [38]. Additionally, the current quick-scan code was written in a way to  
501 have many optional settings. Choosing one preferred yield prediction method or a fixed set of module settings will increase  
502 the speed, thus many *if* statements can be avoided. Moreover, making the coding more efficient, avoiding *for*-loops and a  
503 multitude of Python packages, and converting data back and forth will boost the calculation speed. Lastly, the Random Access  
504 Memory (RAM) usage can be decreased by pre-allocating arrays [39].

505 Roofs could also be categorized by their PV potential. Figure 16 shows the measured annual performance distribution for 236  
506 PV systems. To quickly determine the suitability of the roofs for PV, the systems could be divided based on their  
507 performance. For example, five categories could be created with equal amounts of systems by sorting the PV systems  
508 performances. This will result in four boundaries at 839.1, 911.7, 961.5 and 1012.9 kWh/kWp, respectively. Additional lower  
509 boundary can be set under which a roof is classified unsuitable. This method is easy to implement, however, in reality the PV  
510 potential is not the only variable influencing the decision of the roof owner. This method can be extended by applying a  
511 minimum amount of fitted modules to the results found by the quick-scan. If only one or two modules were fitted, it might still  
512 not be feasible to install them, since installation costs will be relatively high.

513 Besides kWh/kWp as the only metric for roof suitability for PV, a system design can be rated based-on performance,  
514 installation, and aesthetic aspects (as decision-making process factors). A grading system was proposed based on a fast elitist  
515 non-dominated sorting genetic algorithm for multi-objective optimization, first published by [40]. This algorithm could be  
516 implemented to categorize the PV systems that were designed on roofs by the quick-scan algorithm.

## 5.2. Conclusion

This research aimed to develop a method that can quickly scan the PV potential of many roofs with a high precision in a short amount of time. The paper introduced the approaches used for each stage of the quick-scan method (3D roof segment reconstruction, automatic module fitting, and yield calculation). The method was tested using a dataset of rooftop PV systems located in the Netherlands.

A simple and fast approach to determine the roof segment orientation was developed, based on the longest side of the roof segment polygon. For the set of 520 roof segments, the absolute error was found to be within  $6.3^\circ$  for 95% of the pitched segments. Most of the deviation were caused by the non-rectangular roof segments.

For a studied set of 145 roofs and 215 roof segments, module placement was underestimated by 17.5% on average. Multiple reasons were identified for fewer modules being fitted than actually installed: (1) over or under-segmentation, (2) different module layout, size, and spacing from roof edges, (3) different module tilt and spacing on flat roofs, and (4) modules of one PV system spread over multiple building roofs. In terms of RSD, the obstacle-including approaches (SM and PVMD) outperformed the PVGIS yield calculation. It is concluded that using only one obstacle view might cause inaccuracy for large roof segments, especially if the least shaded part of a large roof is used, this can lead to under-prediction of the PV system performance by the quick-scan method.

To demonstrate the added benefit of 3D roof segment data over 2D land register data, the module fitting and yield prediction were also carried out. The performance predictions using the SM yield prediction method were widely spread with an RSD of 20.4%, while those using the PVGIS method were relatively constant at 1070 kWh/kWp per year. The added value of 3D roof segments was thus shown.

For the quick-scan method, the required calculation times per roof for SM, PVMD, and PVGIS were around 28, 26 and 6 seconds, respectively.
