Abstract: Electrochemical CO₂ reduction holds great promise in reducing atmospheric CO₂ concentration. However, several challenges hinder the commercialization of this technology. Energy efficiency, CO₂ solubility in aqueous phase, and electrode stability are among the current issues. In this mini-review, we summarize and highlight the main advantages and limitations that Metal-Organic Frameworks may offer to this field of research, either when used directly as electrocatalysts or when used as catalyst precursors.

1. Introduction

The ever-increasing atmospheric CO₂ concentration is one of the critical issues that require an urgent solution within this century. From a global carbon cycle point of view, industrial activity is the major CO₂ contributor, causing a rapid accumulation of this greenhouse gas in the atmosphere. To counteract this unbalance, CO₂ capture and utilization technologies should be implemented. In this spirit, several technologies have been proposed for CO₂ utilization, based on thermocatalysis, photocatalysis, and electrocatalysis, *etc.* All the above-mentioned catalytic approaches have their economic advantages under certain conditions, and they may all contribute to reducing atmospheric CO₂.^[1] For example, thermocatalysis would already be economically competitive if green H₂ (*e.g.* generated from water splitting using renewable energy) was massively available.^[2] Photocatalysis, on the other hand, would be more favorable in remote locations with strong solar irradiation. Electrocatalytic reduction of CO₂ (CO₂ER) is the other technology that holds great promise if efficient electrocatalysts can be developed for the direct transformation of CO₂ into valuable products.

Initially, catalysts used for CO₂ER were pure metal foils directly used as electrodes.^[3] With the advancement of nanotechnology, other configurations have been used as catalysts in CO₂ER, significantly enhancing CO₂ER efficiency.^[4] In these nanostructured electrocatalysts, the active phase is dispersed within a conductive support, such as carbon cloth, carbon paper or glassy carbon. In the following context, the electrode mainly refers to catalysts dispersed on a conductive support, and catalyst engineering represents the engineering effort to improve CO₂ER efficiencies (including Faradaic efficiencies toward valuable products, current densities, and energy efficiencies) through the design of catalytic sites and/or the optimization of the catalyst structure.

Metal-organic frameworks (MOFs) have recently emerged in the

field of catalysis because of their unique textural and topological properties.^[5] On the one hand, when MOFs are used directly as catalysts, not only the atomically dispersed metal nodes can be engineered into active sites, but also the organic linkers hold great potential as catalytic sites.^[6] Besides, the porous structure can be tuned to enhance mass transport. On the other hand, MOFs can also be used as catalyst precursors, yielding MOF mediated catalysts.^[7] Following this approach, the MOF is decomposed under controlled conditions to lead to the clustering of its metal component into small nanoparticles or to the formation of single atom catalytic sites. At the same time, the organic component (the linker) rearranges into a carbonaceous matrix that may be conductive.^[8] Xia *et al.* reviewed the use of MOFs for electrochemical energy storage, including catalytic electrodes.^[9] Herein, we summarize the recent works on electrochemical CO₂ reduction using MOF and MOF derived catalysts.

Next to reviewing the work done so far on this interesting topic, we have to realize that the commercialization of CO₂ER will not solely rely on catalyst engineering. Indeed, the design of the electrochemical cell and the optimization of reaction conditions (pressure, temperature, *etc.*) will play a role as important as that of the catalyst itself.

In this mini-review, we first give a brief introduction to the challenges faced by CO₂ER, followed by a summary on MOF-related catalyst engineering and MOF derived electrocatalysts. We finalize with our personal opinion on future developments.

Riming Wang received his MSc degree (2015) from College of Material Science and Engineering at Shandong University. In 2015, he joined the Department of Chemical Engineering at Delft University of Technology as a PhD student, under the supervision of Prof. Freek Kapteijn and Prof. Jorge Gascon. His research focuses on MOF-mediated catalyst engineering for CO₂ electrochemical reduction and MOF photocatalysis.

Freek Kapteijn (1952), MSc in Chemistry and Mathematics, received his PhD in 1980 at the University of Amsterdam. After post-doc positions (Coal Science) in Amsterdam and Nancy (ENSIC), he became Associate professor in Amsterdam. Moved to Delft University of Technology in 1992, was appointed 'Anthonie van Leeuwenhoek professor' in 1999, and chaired from 2008 till 2019 the Catalysis Engineering team. Holds the prestigious Golden Hoogewerff award and is among the highly cited 'Cross-Field' scientists 2018. Research interest focuses on the interplay of catalysis and engineering, comprising structured and multifunctional catalysts, adsorption, separation and (catalytic) membranes. Co-authored over 650 publications in peer-reviewed journals and as book chapters.

Born in Huesca (Spain) in 1977, Jorge received his MSc. in Chemistry in 2002 and his PhD in Chemical Engineering in 2006, both at the University of Zaragoza (Spain). He was post-doc (2006 to 2009), Assistant Professor (2010 to 2012), Associate Professor (2012 to 2014) and Antoni van Leeuwenhoek Professor (2014 – 2017) of Catalysis Engineering at TUDelft (NL). Since 2017 he is Professor of Chemical and Biological Engineering and Director at the KAUST Catalysis Center.

Gascon is a member of the board of the International Zeolite Association Commission on Metal Organic Frameworks. He has been the recipient of the 2013 ExxonMobil Chemical European Science and Engineering Award and he is a 2018 Clarivate Analytics highly cited researcher. His research focuses on the development of sustainable technologies for the production of chemicals, energy carriers and new environmental applications.

2. Main challenges for CO₂ER

CO₂ electrochemical reduction can be seen as a reversed process of fuel cells, and a lot of similarities are shared between these two processes, such as cell configuration, electrolyte, etc. CO₂ER with H-cell, one of the most popular cell configurations so far, features cathode and anode compartments filled with aqueous electrolyte and separated by a membrane. MOFs and MOF-derived catalysts are mostly particles, and are used as supported catalysts in CO₂ER cells. CO₂ approaches the catalytic sites through diffusion in aqueous phase, and several valuable products can be generated, such as CO, C₂H₄, HCOOH, oxalic acid, alcohols, etc. As proposed by Koper and coworkers,^[10] the reduction of CO₂ starts with the formation of a ·COO⁻ intermediate. Subsequent reaction with a proton-electron pair leads to the formation of HCOO⁻, while the absorption of only a proton results in the formation of ·COOH, which will be further reduced to ·CO. On the one hand, if the ·CO intermediate is strongly bonded by the catalyst, for example Cu, it will be reduced to additional products. On the other hand, if the ·CO intermediate is weakly bonded (i.e. in case of Ag, Au or Zn) CO will desorb and become the main product.

The challenges of CO₂ER have been generally summarized and discussed,^[1, 11] so we will only give a brief introduction to CO₂ER here, with specific emphasis on commercializing considerations.

2.1. Overpotential (voltage efficiency)

One of the key drawbacks that hinder the commercialization of CO₂ER is energy efficiency, which is primarily limited by the high overpotential of CO₂ER.

In electrochemistry, overpotential is the potential (voltage) difference between a half-reaction's reduction potential at thermodynamic equilibrium and the potential at which the redox reaction occurs. The existence of overpotential implies that more energy is required than thermodynamically needed to drive a given reaction, and this energy loss, usually in thermal form, directly affects voltage efficiency.

It is widely accepted that the overpotential for CO₂ electrochemical reduction originates from the sluggish kinetics to form a ·CO₂⁻ intermediate.^[11a, 11c] This step has a standard potential of -1.9 V vs. SHE and is the main reason for high overpotentials. This potential can be improved (lowered) by stabilizing the intermediate, which is one of the primary functions of catalysts.

2.2 Faradaic efficiency (FE)

Faraday efficiency is described as energy losses in the current term. Although all the current in CO₂ER is consumed to form products, the current directed toward undesirable reactions or products is usually considered as energy loss.

One primary undesirable product is H₂, generated by the competing hydrogen evolution reaction (HER) in the aqueous electrolyte. As a consequence, catalysts with high hydrogen overpotentials typically give favorable FE for CO₂ER.

From a commercialization perspective, the potential market of CO₂ER will be fuel and commodity chemicals, where oil derived products are now dominating. Taking the competition between CO₂ER derived chemicals and petrochemicals into consideration, it is clear that some CO₂ER products, for example CH₄, are economically unfavorable. Formation of these products should be avoided since the electricity cost to produce them will not be paid off.^[1]

A scenario of CO₂ER commercialization would be the direct treatment of post-combustion gas from power plants, avoiding in this case expensive (and highly energy consuming) separation. These streams usually contain a relatively high concentration of unreacted O₂. Thus, CO₂ER catalyst for this specific application should be inactive toward oxygen reduction reaction (ORR).^[12] Moreover, the ORR products are reactive O₂⁻ and H₂O₂ species sometimes, which offer a harmful environment for CO₂ER catalysts.^[13]

2.3 CO₂ mass transport

One of the key limiting factors in aqueous-phase CO₂ conversion is the mass transfer of CO₂ to the cathode surface, especially given the low solubility of CO₂ in many electrolytes. In addition to catholyte CO₂ capacity, product bubble formation can disrupt the reaction system as well. Although the low solubility of CO₂ in aqueous phase can be overcome by using gas-diffusion electrodes (GDE), the current density of cathode GDEs may also be limited by the CO₂ flux to the catalyst. The CO₂ transport limit can be seen as the critical issue that hinders the enhancement of current density.^[14] Configuration of electrochemical cells may largely influence the CO₂ transportation, and in turn influences the current density, thus it

For internal use, please do not delete. Submitted_Manuscript

should be noted that the comparison of current densities should take the cell configuration into consideration.^[15]

2.4 Electrode stability

Stability is an essential criterion for commercial catalysts. Excellent stability can greatly reduce the operational costs.^[16] In CO₂ER, the electrode stability requires not only the resistance to deactivation but also the resistance to impurities.^[17] The long-time running of CO₂ER has been reported in several articles.^[18] However, the resistance to impurities has not been widely covered. Again, taking the example of using the post-combustion gas from power plant as CO₂ feedstock, the post-combustion gas will contain a relatively high level of impurities, such as SO_x and NO_x, even after a primary treatment, and S has been identified as a harmful component to many electrocatalysts.^[19] The electrolyte is another source of impurities.^[11c, 20] In this regard, more research into impurity-resistant electrodes will be important. Additionally, electrode stability should be separated from system stability. For instance, electrode clogging because of the formation of bicarbonate crystals during CO₂ER is not related to the electrode itself but to the reactor system and such should be solved through system engineering.

3. MOF-related catalysts for CO₂ER

Table 1. Summary of CO₂ER performance with MOF-related materials.

Electro-catalyst ^[a]	Main product	Peak FE ^[b] (%)	Peak j_{total} (mA cm ⁻²)	Peak potential ^[c] (V)	Electrolyte
CR-MOF ^[21]	Formic acid	~100	7.1	-0.78	0.5 M KHCO ₃

MOFs, combining the favorable characteristics of heterogeneous and homogeneous catalysts, have been explored as a novel class of model catalytic materials for understanding the electrochemical CO₂ reduction.

The application of MOF-related catalysts for CO₂ electrochemical reduction started in 2012,^[21] when a copper rubeanate metal-organic framework (CR-MOF) was prepared by Hinogami *et al.* to electrochemically reduce CO₂ into valuable products. With an onset potential of \sim 200 mV more positive than that of a Cu electrode in the aqueous electrolyte, formic acid (HCOOH) was virtually the only CO₂ reduction product (FE = \sim 100%), whereas various products were generated on a Cu electrode. The partial current of HCOOH by CR-MOF electrode was \sim 7.1 mA cm⁻², which was also higher than for the Cu electrode.

Kumar *et al.*, also in 2012, reported cyclic voltammetry (CV) studies in 0.1 M KCl of Cu-BTC films on glassy carbon electrodes.^[22] Well-defined Cu(II)/Cu(I) and Cu(I)/Cu(0) reversible redox responses were observed. The MOF film was then studied as electrocatalyst in N,N-dimethylformamide (DMF). The production of oxalic acid was confirmed by GC-MS with a FE of \sim 51% and a total current density of 19 mA cm⁻².

Following these pioneering works, additional MOF-based catalysts have been investigated for CO₂ER. ZIF-8, an archetypical MOF material, was synthesized with various zinc sources by Wang *et al.* and used as electrocatalyst for CO₂ reduction to CO.^[23] ZIF-8 prepared with ZnSO₄ delivered the best catalytic activity towards CO₂ electroreduction, with a FE toward CO (FE_{CO}) of 65% and a total current density (j_{Total}) of \sim 3 mA cm⁻², establishing a relation between the CO₂ER performance and synthetic zinc sources. The main catalytic active sites were claimed to be the discrete Zn nodes in ZIF-8.

Jiang *et al.* further identified the imidazolite ligands coordinated with the Zn(II) center in ZIFs as the catalytic sites of ZIFs for

CO₂ER with the help of in-situ X-ray absorption spectroscopy (XAS) measurements and density functional theory (DFT) calculations.^[24] They investigated ZIFs with the same sodalite topology and different organic ligands, including ZIF-8, ZIF-108, ZIF-7, and SIM-1 for CO₂ER in aqueous electrolyte. ZIF-8 showed the highest FE_{CO} of 81.0% at -1.1 V vs. RHE among all the ZIF catalysts, and the CO current density could reach as high as 12.8 mA cm⁻² at -1.3 V vs. RHE over ZIF-108.

The effect of the linker on CO₂ER was also investigated^[25] by Albo *et al.* Four Cu-based MOFs, namely, 1) Cu-BTC (HKUST-1); 2) Cu-AdeAce; 3) Cu-DTA mesoporous metal-organic aerogel (MOA); and 4) CuZn-DTA MOA, were synthesized and supported on gas diffusion electrodes. The MOF-based electrodes showed electrocatalytic efficiency for the production of methanol and ethanol in the liquid phase. The maximum cumulative FE for CO₂ conversion was measured at Cu-BTC based electrodes, which was 15.9 % at a current density of 10 mA cm⁻². It was demonstrated that MOFs with coordinately unsaturated metal sites were favorable for the enhancement of the electrocatalytic reduction of CO₂ to alcohols. Furthermore, Cu-BTC based electrodes showed stable electrocatalytic performance for 17 h.

In addition to the structural effect, the linker of MOFs can also be functionalized to boost the catalytic activity. The poor conductivity of MOFs largely hinders their direct application as electrocatalysts, thus, Dou *et al.* reported a general strategy of ligand doping to enhance charge transfer, thereby improving the electrocatalytic activity.^[26] A strong electron-donating molecule, 1,10-phenanthroline, was introduced into ZIF-8 as CO₂ reduction electrocatalyst. Experimental and theoretical results suggested that the electron-donating nature of phenanthroline enabled charge transfer, which facilitated the generation of \cdot COOH. As a consequence, the ligand-doped ZIF-8 showed an FE_{CO} of 90% and a j_{Total} of 10.1 mA cm⁻², both significantly improved compared with pristine ZIF-8.

Ye *et al.* deposited a highly oriented monolithic Re-based MOF thin film onto a conductive FTO electrode using liquid-phase epitaxy.^[27] The MOF film was grown exclusively along the [001] direction, and exhibited a high FE_{CO} of \sim 93% when operated as an electrocatalyst for the reduction of CO₂, with a current density exceeding 2 mA cm⁻².

As discussed above, the overpotential is one of the key issues which needs to be addressed in CO₂ER. A combination of ionic liquids (ILs) as the electrolyte and Zn-BTC as the catalyst was applied by Kang *et al.* as a strategy to lower overpotentials in CO₂ER,^[28] which was the first work combining a MOF electrode and pure IL electrolyte in this field. The Zn-BTC electrode showed a higher selectivity to CH₄ (>80%) and higher current density (3 mA cm⁻²) at mild overpotentials (250 mV), than the commonly used metal electrodes.

3.2 MOFs as active phase supports

For internal use, please do not delete. Submitted_Manuscript

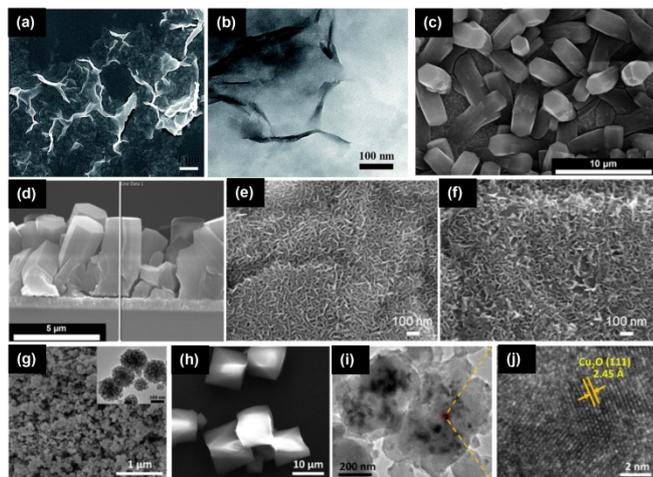

Figure 2. Representative electron micrograph of using MOF as catalyst supports. (a) SEM image and (b) TEM image of $\text{Cu}_2(\text{CuTCPP})$ nanosheets;^[31] Top-view SEM images (c) and cross-sectional SEM image (d) of the Cu-SIM NU-1000 thin film;^[34] SEM images of the MOF catalyst film before (e) and after electrolysis (f) revealing the retention of the plate-like morphology;^[32] (g) SEM and TEM (inset in g) images of Cu_2O spheres, (h) SEM image of Cu-MOF, (i) TEM and (j) HRTEM images of $\text{Cu}_2\text{O}@$ Cu-MOF after reacting for 12 h.^[35]

In addition to the direct application as electrocatalysts, the unique textural properties of MOFs also offer a number of opportunities for their application as active phase supports for CO_2ER .

Porphyrin-based molecular catalysts have been widely used in CO_2ER .^[47] The significance of molecular catalyst immobilization was highlighted by Hu *et al.* by comparing the performance of cobalt meso-tetraphenylporphyrin (CoTPP) in CO_2ER under both supported and unsupported conditions.^[48] CoTPP performed poorly as a homogeneous electrocatalyst giving low product selectivity at a high overpotential, while a remarkable catalytic activity enhancement was seen with CO_2 selectively forming CO (> 90%) at a low overpotential upon directly immobilizing CoTPP onto carbon nanotubes. Kramer *et al.* demonstrated that the immobilization agent had an effect on the molecular catalyst's performance by comparing the CO_2ER activity of cobalt phthalocyanine (CoPc) supported on edge-plane graphite and poly-4-vinylpyridine (P4VP) thin films.^[49] CoPc embedded in P4VP matrix displayed improved FE_{CO} and turnover frequency, which was attributed to the chemical coordination environment provided by the P4VP polymer matrix.

Hod *et al.* used Fe-porphyrin as CO_2 reduction catalyst, which was incorporated into MOF-525 as both a structural and functional element.^[29] MOF-525 was first deposited onto a conductive ITO substrate, and then Fe-porphyrin was formed via a post-metalation strategy. The approach yielded a high surface coverage of electrochemically addressable Fe-porphyrin sites (~ 1015 sites cm^{-2}), forming a mixture of CO and H_2 in roughly equal amounts ($FE_{\text{CO}} = \sim 50\%$) as products with a j_{Total} of ~ 6 mA cm^{-2} . In spite of the low FE of CO_2ER , these results demonstrated that porphyrins can be electrochemically accessed when incorporated into a MOF structure.

Electroactive porphyrins can also be used as ligands to form MOFs. Dong *et al.* rationally introduced a Fe-TCPP porphyrin to form PCN-222(Fe) as CO_2ER catalyst.^[30] After dip-coating onto carbon substrate, the composite catalyst PCN-222(Fe)/C (mass ratio = 1:2) exhibited a maximum 91% FE_{CO} with 494 mV overpotential (where $j_{\text{Total}} = 1.2$ mA cm^{-2}) in an aqueous solution, achieving a TOF of 0.336 site $^{-1}$ s $^{-1}$. The catalyst was found to retain its crystallinity and stability after 10 h of electrolysis at -0.60 V versus RHE (average $FE_{\text{CO}} = 80.4\%$).

Wu *et al.* used porphyrinic MOF nanosheets for CO_2ER .^[31] The $\text{Cu}_2(\text{CuTCPP})$ nanosheets were cathodized on FTO glasses, and exhibited significant activity for formate production with a FE of 68.4% at -1.55 V vs. Ag/Ag $^+$. Moreover, the C-C coupling product acetate was also generated from the same catalyst at a voltage range of 1.40 - 1.65 V with the total liquid product FE of 38.8 - 85.2%. Characterization results showed the instability of $\text{Cu}_2(\text{CuTCPP})$, with Cu(II) being transformed into CuO, Cu_2O and Cu_4O_3 , which significantly catalyzed CO_2 to formate and acetate.

Kornienko *et al.* employed an aluminium porphyrin-based MOF-55,^[32] comprising cobalt porphyrin active sites, for the electrocatalytic reduction of CO_2 to CO. An aluminium oxide thin film was first deposited via atomic layer deposition (ALD) as metal precursor, followed by subsequent MOF formation through the reaction of the coated aluminium oxide with the linker under solvothermal conditions. The thickness of the precursor could easily be controlled by the number of ALD cycles, thereby controlling the thickness of catalyst layers. The performance of the resulting MOF catalyst initially improved with increasing film thickness until reaching a maximum of ~ 2.8 mA cm^{-2} , and the appearance of maximum performance possibly indicated a trade-off between electron and mass transport. The optimized catalyst thickness exhibited a FE_{CO} production of up to 76 % in a 7 h test.

In addition to molecular catalysts, MOFs have also been used for supporting metal nanoparticles in CO_2ER . Jiang *et al.* reported the construction of $\text{Ag}_2\text{O}/$ layered ZIF composite structure by mixing pre-synthesized layered ZIF-7 with AgNO_3 aqueous solution, followed by refluxing at 100 $^\circ\text{C}$.^[33] $\text{Ag}_2\text{O}/$ layered ZIF composite showed much higher FE_{CO} ($\sim 80\%$) and j_{CO} (~ 32 mA cm^{-2}) than the layered ZIF or Ag/C alone. The performance enhancement was attributed to the synergistic effect between Ag_2O nanoparticles and the layered ZIF, as well as the facilitated mass transport by the high specific surface area of $\text{Ag}_2\text{O}/$ layered ZIF.

Kung *et al.* embedded copper nanoparticles into a thin film of NU-1000,^[34] by first installing single-site Cu(II) into the NU-1000 thin film followed by electrochemical reduction of Cu(II) to metallic Cu. The obtained Cu nanoparticles were electrochemically addressable and exhibited a moderate electrocatalytic activity with a maximum FE toward HCOO^- of 28 % and -1.2 mA cm^{-2} at -0.82 V vs. RHE. Both the crystallinity and morphology of the thin film remained unchanged after electrocatalysis. The authors also found that the particle sizes were largely dependent on the pore size of the MOF, which might offer an opportunity to achieve tunable catalyst sizes through this pore confinement effect of MOFs.

For internal use, please do not delete. Submitted_Manuscript

In a recent study, Tan *et al.* reported a tailor-made Cu₂O@Cu-MOF electrocatalyst,^[35] by in-situ etching Cu₂O spheres with H3BTC to form a Cu-MOF shell. The as-prepared electrocatalyst resulted in an intriguing performance towards the formation of hydrocarbons from CO₂, with a high FE toward CH₄ and C₂H₄ of 79.4%, particularly, the FE of CH₄ as high as 63.2% at -1.71 V.

3.3 MOF as electrocatalyst precursors

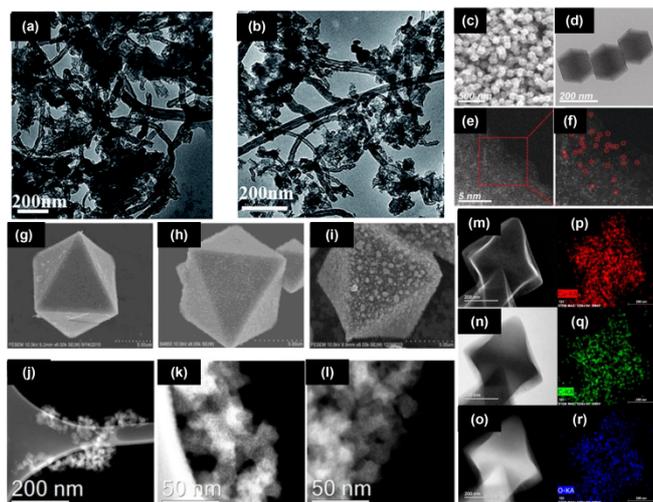

Figure 3. Representative electron micrograph of using MOF as catalyst precursors. TEM images of (a) ZIF-CNT-FA-p, and (b) ZIF-Fe-CNT-FA-p.^[46] (c) SEM and (d) TEM images of N-coordinated Co. Although quite a few works using MOFs directly as catalysts claimed that the MOF catalysts showed good stability during test, a lot of them failed to conduct post-reaction analysis to confirm these statements.^[50] Indeed, stability is a serious issue for MOFs, especially under the highly negative potentials usually applied in CO₂ER. These potentials are more negative than the reduction potential of many metals used in MOF synthesis (see Table 2). In this spirit, using a MOF as catalyst precursor can be a favorable way to produce a stable and efficient catalyst.

Table 2. Standard electrode potentials of common metal nodes in MOFs.^[51]

Half reaction	Potential (V vs. RHE)
$\text{Co}^{3+} + \text{e}^- \rightleftharpoons \text{Co}^{2+}$	1.82
$\text{Ag}^+ + \text{e}^- \rightleftharpoons \text{Ag}$	0.8
$\text{Fe}^{3+} + \text{e}^- \rightleftharpoons \text{Fe}^{2+}$	0.77

$\text{Cu}^+ + \text{e}^- \rightleftharpoons \text{Cu}$	0.52
$\text{O}_2 + 2\text{H}_2\text{O} + 4\text{e}^- \rightleftharpoons 4\text{OH}^-$	0.4
$\text{Cu}^{2+} + 2\text{e}^- \rightleftharpoons \text{Cu}$	0.34
$\text{Cu}^{2+} + \text{e}^- \rightleftharpoons \text{Cu}^+$	0.15
$2\text{H}^+ + 2\text{e}^- \rightleftharpoons \text{H}_2$	0
$\text{Fe}^{3+} + 3\text{e}^- \rightleftharpoons \text{Fe}$	-0.04
$\text{Ni}^{2+} + 2\text{e}^- \rightleftharpoons \text{Ni}$	-0.25
$\text{Co}^{2+} + 2\text{e}^- \rightleftharpoons \text{Co}$	-0.29
$\text{Fe}^{2+} + 2\text{e}^- \rightleftharpoons \text{Fe}$	-0.41
$\text{Cr}^{3+} + \text{e}^- \rightleftharpoons \text{Cr}^{2+}$	-0.42
$\text{Cr}^{3+} + 3\text{e}^- \rightleftharpoons \text{Cr}$	-0.74
$\text{Zn}^{2+} + 2\text{e}^- \rightleftharpoons \text{Zn}$	-0.76
$\text{Ti}^{3+} + 3\text{e}^- \rightleftharpoons \text{Ti}$	-1.37
$\text{Zr}^{4+} + 4\text{e}^- \rightleftharpoons \text{Zr}$	-1.45
$\text{Ti}^{2+} + 2\text{e}^- \rightleftharpoons \text{Ti}$	-1.63
$\text{Al}^{3+} + 3\text{e}^- \rightleftharpoons \text{Al}$	-1.66

The decomposition of MOFs under controlled conditions usually leads to the clustering of its metal component into small nanoparticles. Zhao *et al.* synthesized oxide-derived Cu/carbon (OD Cu/C) catalysts by facile carbonization of Cu-BTC MOF (HKUST-1).^[36] The resulting materials exhibited highly selective CO₂ reduction to alcohols with total FE of 71.2% at -0.7 V vs. RHE. High yields to methanol and ethanol were achieved on OD Cu/C-1000 with the peak production rates of 12.4 mg L⁻¹ h⁻¹ at -0.3V and 13.4 mg L⁻¹ h⁻¹ at -0.7V, respectively. Notably, the onset potential for C₂H₅OH formation was among the lowest overpotentials reported to date for the CO₂ reduction to C₂H₅OH. The improvement in activity and selectivity of the oxide-derived Cu/carbon were attributed to the synergistic effect between the highly dispersed copper and the matrix of porous carbon. Kim *et al.* used an electrochemical reduction strategy to decompose MOFs,^[37] obtaining an efficient electrocatalyst for the synthesis of CH₄. Cu-based MOF-74 was chosen as the precursor, which was electrochemically reduced to Cu nanoparticles (NPs). The porous structure of the MOF serves as a template for the synthesis of isolated Cu NPs with high current densities and high FE toward CH₄ in the electrochemical CO₂ reduction reaction. The MOF-derived Cu NPs resulted in a

For internal use, please do not delete. Submitted_Manuscript

$FE_{CH_4} > 50\%$ and a 2.3-fold higher current density at -1.3 V vs. RHE than commercially available Cu NPs.

Besides metal nanoparticles, MOF-mediated synthesis can also act as a method to generate isolated metal-nitrogen sites with high exposure of active sites for efficient catalysis. Ye *et al.* fabricated isolated iron-nitrogen sites, located on the surface of carbon matrix, through the pyrolysis of ammonium ferric citrate (AFC)/ZIF-8 composites.^[38] The AFC/ZIF-8 composite was synthesized by reacting the Zn precursor solution, in which the AFC was also dissolved, with 2-methylimidazole solution, followed by cleaning, centrifuging, and drying. The highly exposed iron-nitrogen sites demonstrated high selectivity to CO (peak $FE_{CO} = 93\%$) and high activity ($j_{CO} = 9.5$ mA cm⁻²).

Zhao *et al.* adopted Ni ion exchanged ZIF-8 to assist the preparation of a catalyst containing single Ni sites for efficient CO₂ electroreduction.^[39] The synthesis was based on an inexpensive ionic exchange between Zn nodes and adsorbed Ni ions within the cavities of the MOF, which was followed by pyrolysis of the ion-exchanged MOF. This single-atom catalyst exhibited an outstanding turnover frequency for CO₂ electroreduction (5273 h⁻¹), with a FE_{CO} of over 71.9% and a j_{Total} of 10.48 mA cm⁻² at an overpotential of 890 mV.

Pan *et al.* studied the reactivity and structure of atomically dispersed M-N₄ (M = Fe and Co) single sites in CO₂ER. Nitrogen coordinated Fe or Co single site atomically dispersed into a carbon matrix (M-N-C) were prepared by using MOF precursors which were further studied as model catalysts.^[40] Fe was intrinsically more active than Co in M-N₄ for the reduction of CO₂ to CO, in terms of a higher FE_{CO} (93% vs. 45%) and current density. First principle computations elucidated that the M-N₂₊₂-C₈ moieties, which were distributed at the edge of carbon matrix and bridged two adjacent armchair-like graphitic layers, were the active sites for the CO₂ER.

Selectivity is one of the key issues faced by CO₂ER, especially when Cu-based catalysts are used. Nam *et al.* reported a strategy involving MOF-regulated Cu cluster formation that shifted CO₂ electroreduction with Cu based catalysts towards multiple-carbon products.^[41] The symmetric paddle-wheel Cu dimer secondary building block of HKUST-1 was distorted to an asymmetric motif by separating adjacent benzene tricarboxylate moieties using thermal treatment. By varying materials processing conditions, the asymmetric local atomic structure, oxidation state and bonding strain of Cu dimers were modulated. The formation of Cu clusters with low coordination numbers from distorted Cu dimers in HKUST-1 was observed during CO₂ electroreduction, leading to a FE toward C₂H₄ of 45%. The enhanced performance was closely related to maintaining a low Cu-Cu coordination number among the Cu clusters during the reaction.

Another example of regulating coordination number to tune the selectivity was reported by Wang *et al.*^[42] A series of atomically dispersed Co catalysts with different nitrogen coordination numbers were prepared for the CO₂ER. The best catalyst, atomically dispersed Co with two-coordinate nitrogen atoms, achieved both high selectivity ($FE_{CO} = 94\%$) and superior activity ($j_{Total} = 18.1$ mA cm⁻²) at an overpotential of 520 mV. The CO formation turnover frequency reached a record value of

18200 h⁻¹. These results demonstrated that lower a coordination number facilitated activation of CO₂ to the •COO⁻ intermediate and hence enhanced CO₂ER activity.

Very recently, Guo *et al.* introduced a new method to tune the CO₂ER selectivity via MOF-derived bimetallic oxide catalyst.^[43] MOF-derived In-Cu bimetallic oxides were synthesized by pyrolysis of a Cu-In bimetallic MOF. By controlling In-Cu ratios, the FE_{CO} could reach 92.1%, along with a j_{Total} of 11.2 mA cm⁻². The excellent performance was mainly attributed to stronger CO₂ adsorption, higher electrochemical surface area and lower charge transfer resistance by the bimetallic catalyst.

Besides metal-based catalysts, a carbon-rich organic linker, combined with the low-boiling point of some metal nodes, such as Zn, make MOFs a promising precursor to produce carbon-based electrocatalysts.^[52] Following this strategy, Wang *et al.* synthesized a nitrogen-doped carbon (NC), through the pyrolysis of the well-known metal-organic framework ZIF-8.^[44] The resulting NC-based CO₂ER electrode showed a FE_{CO} as high as ~78%. It was also found that the pyrolysis temperature determined the amount and the accessibility of N species in the carbon electrode, in which pyridinic-N and quaternary-N species played key roles in the selective formation of CO. Generally the materials derived from Zn-based ZIFs are nothing less than nitrogen containing carbons and are active without other metal addition. Therefore it should be kept in mind to benchmark their performance against those materials prepared via other routes.^[53]

The pyrolysis temperature effect and the mechanism in the ZIF-8-derived NC was further studied by Zheng *et al.*^[45] NC catalysts were prepared by decomposing ZIF-8 at different temperatures in argon. The catalytic performances showed that the higher pyrolysis temperature resulted in a better CO₂ER activity. The NC catalyst with the best performance achieved high selectivity with 95.4 % FE_{CO} at -0.5 V vs. RHE. The catalyst also maintained stability during 20 h operation, after which the FE_{CO} was still greater than 90%. The experiments showed that a higher pyrolysis temperature reduced the total nitrogen contents but changed the nature and density of N-species. DFT calculations revealed that higher pyrolysis temperature led to enhanced activity by promoting the formation of pyridinic N, which provided more efficient active sites.

To relieve the electron transportation limit with MOF-mediated approach, Guo *et al.* synthesized a composite material by co-pyrolysis of in-situ grown ZIF-8 on multi-walled carbon nanotubes (MWCNTs) substrate.^[46] This composite could selectively catalyze the electrochemical reduction of CO₂ to CO in aqueous solution with ~100 % FE and a current density up to 7.7 mA cm⁻² at an overpotential of 740 mV. By comparison, the pyrolyzed ZIF-8 without MWCNT only showed a FE_{CO} of ~50%. Addition of Fe to the ZIF could lower the overpotential, but also changed the selectivity. The MWCNT support was crucial to achieving superior efficiency, by enhancing electron transport through the MWCNT network and simultaneously expediting the CO₂ transport in the mesoporous structure constructed by the MWCNTs.

4. Concluding remarks

CO₂ER is widely regarded as one of the most promising technologies to solve the CO₂ emission issue, though it is still faced by several challenges on the path toward commercialization. In this work, we have summarized recent works on CO₂ electroreduction with MOFs and MOF mediated catalysts. Generally speaking, the main advantages of MOFs in CO₂ER originate from their unique textural and structural properties. When MOFs are used directly as catalysts for CO₂ER, the atomically dispersed metal nodes can offer highly active sites, and the organic linkers can also be modified into catalytic sites or charge transfer agents. The porous structure, put up by the metal nodes and organic linkers, makes catalytic sites more accessible to CO₂ either if catalysis takes place on the MOF itself or on supported species. Moreover, the compatibility of MOFs with ILs facilitates their application in this medium. The use of MOFs as catalyst precursors usually leads to highly dispersed metal particles or carbon-based catalysts, maximizing catalyst utilization. The homogeneously dispersed metal sites can be inherited by the MOF-derived catalysts to form efficient single-site catalysts with unprecedented TOFs. And the highly tunable building blocks of MOFs enable the formation of bi-metallic structures, providing a facile route to the synthesis of metal alloys, opening the door to breaking scaling relationships in CO₂ER.^[10]

Although remarkable results have been reported with MOF-related catalysts, there are still issues that need to be carefully addressed in future research. Stability is one of the most concerning issues for CO₂ER. While most authors have claimed that pristine MOFs based on easily reducible metals are stable under reaction conditions, the catalyst stability has only been confirmed in a few cases by post-analysis characterization.^[30, 32, 34-35] Here, we would like to clarify that stability of the crystalline MOF does not necessarily need to be an issue. Indeed, from an application point of view, electrochemical reduction of MOFs to form small metal nanoparticles may render very interesting catalytic systems. However, as scientists, we should make sure that we do not jump into wrong conclusions by attributing the observed catalytic performance to the MOF scaffold.

As it is the case in thermal catalysis, probably the most exciting results in terms of performance have been reported for MOF-derived catalysts.^[7a, 54] We believe that this route offers great possibilities for the further engineering of CO₂ER catalysts and for the optimization of metal use in catalysis, an aspect that may become critical if CO₂ electrolyzers are massively applied.

Last but not least, it is fair to admit that so far most catalytic results have been reported using aqueous electrolytes and semi-batch experiments, where only low current densities can be achieved due to the low solubility of CO₂ in aqueous phase. We are sure that, as it is already happening for "traditional" electrocatalysts, MOF-derived systems will soon be tested under commercially more relevant conditions by making use of gas-diffusion electrochemical cells in which high current densities (>100 mA cm⁻²) have been achieved.^[55] Through carbon capture technologies from point sources liquid CO₂ will become available at pressures exceeding 100 bar and solubility may not be

limiting any more. Also aspects of molecular and electron transport require careful attention, as shown by Guo *et al.*^[46] Overall, we are confident that MOF-related catalysts engineering when combined with system integration of CO₂ER, will mark a substantial contribution to the field of electrocatalytic CO₂ reduction.

Abbreviations

BTC	Benzene-1,3,5-Tricarboxylate
CN	Coordination Number
CR-MOF	Copper Rubeanate Metal-Organic Framework
FE	Faradaic efficiency
HER	Hydrogen evolution reaction
MWCNT	Multi-walled Carbon Nanotube
NC	Nitrogen-doped Carbon
ORR	Oxygen reduction reaction
Pc	Phthalocynine
P4VP	Poly-4-vinylpyridine
PCN	Porous Coordination Network
RHE	Reversible hydrogen electrode
SHE	Standard hydrogen electrode
SIM	Substituted Imidazolate Material
TBAH	Tetrabutylammonium hydroxide
TCPP	Tetrakis(4-carboxyphenyl)porphyrin
TOF	Turnover frequency
ZIF	Zeolitic Imidazolate Framework
